Discussion

Although findings from a number of recent case-control studies demonstrate a strong association between workplace exposures (high repetition, high force, vibration) and carpal tunnel syndrome,[7–11] this is the first population-based study to report age-, sex- and industry-specific incidence rates of OCTS. The mean age and female/male gender ratio (37.4 years; F:M = 1.2:1) of the OCTS population reported here differ dramatically from that reported for non-occupational carpal tunnel populations (51 years; F:M = 3:1).[12,13] These clear demographic differences between the occupational and non-occupational CTS populations, as well as the magnitude of numbers reported here, would appear to support the concept that workplace exposures may be responsible for a substantial proportion (up to 47 percent)[1] of physician-reported carpal tunnel cases.

The highest incidence rate reported here for shellfish packing (25.7 claims/1,000 FTEs) is similar to the highest reported incidence rates of "potential" carpal tunnel cases using Wisconsin WC data.[3] Industry-specific rates would be expected to vary according to the distributions of industries in each state or region. Some of the highest rates reported here are very characteristic of Washington State (seafood processing and canning, logging and wood products manufacturing, boat building), whereas others are represented in many regions and could be used for comparison (meat and poultry processing, carpentry, fruit and vegetable canning, egg production, foundries, wallboard installation, roofing, plastics manufacturing, and construction).

Industries reported in Table 3, sorted by total numbers of cases, represent more modest incidence rates and rate ratios. Rates for some of these industries (retail groceries, clothing manufacturing, printing and lithography, and electric wiring) may involve relatively weak CTS hazards, or may represent dilution of high exposure jobs by increased job diversification in some industries. Others with very high numbers of claims but non-significant rate ratios (e.g. restaurants) or difficult to explain exposures (e.g. convalescent and nursing homes) require further investigation.

Although video display terminal (VDT) operation has been associated with cumulative trauma disorders,[14] its relationship to OCTS has not been documented clearly in the literature. The industrial classes reported here whose claims may be related to VDT exposure (e.g. clerical, state employees, higher education employees) have non-elevated rate ratios. As these industrial classes represent a wide range of occupations, an association between VDT use and CTS may be diluted. Underreporting of cases in pre-

TABLE 5—Diagnostic Coding Errors for OCTS

71.6%	CTS diagnosis codes 354.0 and 354.1
3.4%	Probable CTS secondary to trauma (fracture, burn)
25.0%	ICD codes not specific for OCTS Miscellaneous data entry errors for OCTS

dominantly female job titles might be an alternative explanation for these lower than expected rates.

Rates among females increased significantly during the study period, while rates among males remained stable. The trends could be due to prior underreporting of claims among females or to a shift of women into higher exposure jobs. Because the gender-specific rates reported here depend on extrapolated rather than direct denominators, these conclusions should be validated in other studies.

Potential pitfalls in the use of workers' compensation[15] and other administrative data bases[16] to generate epidemiologic research have been well documented. Serious underreporting of OCTS cases to workers' compensation bureaus,[1,15] a lack of specificity in the current US Department of Labor coding system,[3] and difficulty generating direct denominators[17] present formidable obstacles that will require public policy changes before improvement is realized. We were able to mitigate the effects of the latter two problems by use of physician-generated ICD billing codes and worker hours reported by WIC, respectively.

Misclassification and coding errors are other serious problems in using workers' compensation data. Incidence rates for OCTS presented were subject to error by both overcounting and undercounting. We were able to validate that only 82 percent of incident claims are true cases of carpal tunnel syndrome by documented physician diagnosis in the medical records. This potential source of overcounting, however, was non-differential by age, sex, or year, and using more or less restrictive inclusion criteria for incident claim definition did not reduce the degree of misclassification.

An equally serious source of potential undercounting of incident claims was also encountered, particularly in regard to ICD coding errors. Only 72 percent of unique claims that were associated with carpal tunnel surgery had an ICD code (354.0 or 354.1) compatible with carpal tunnel syndrome. Another 3.4 percent of claims had diagnosis codes that were related to CTS of traumatic origin, but 25 percent of claims had either non-specific diagnoses or erroneous diagnostic codes. The latter cases would not have been captured in this study. No gains in precision could be derived from applying these estimates of misclassification to the OCTS incidence rates.

The WIC system is specific to Washington State and is not directly comparable to the national Standard Industrial Classification (SIC) coding system. We were unable to generate reliable SIC code-specific OCTS rates because employee hours are not reported to L&I by SIC code. The WIC system differs from the SIC system in that the former sets aside a separate classification for some occupations such as clerical workers regardless of the employers principal industry type. However, the WIC and SIC systems of classification are sufficiently similar to allow other investigators indirect comparability.

On balance, and with more complete understanding of the limitations of workers' compensation[15] and administrative data bases,[16] workers' compensation data can be useful in generating population-based data for the purposes of surveillance, forecasting trends, and resource targeting for loss control and prevention. The use of other surveillance systems, dependent on direct physician or laboratory reporting,[18,19] could provide complementary information. Workers' compensation data might be particularly useful in the investigation of occupational conditions for which no other good surveillance systems exist, such as OCTS, morbid head injuries, labor injuries among minors, sexual assaults,[20] or for conditions related to mandatory reporting, such as lead poisoning.[21] □

Acknowledgments

This work was funded by the Accident and Medical Aid Funds of the State of Washington, Department of Labor and Industries. These research monies are targeted to reducing the incidence and disability related to occupational injuries and illnesses. Special thanks are due to Barbara Silverstein, PhD, for critical review of the manuscript, and to Melinda Fujiwara for preparation of the manuscript.

Developmental, Learning, and Emotional Problems Affect 10.7 Million American Children

One in five American children has had a developmental delay, learning disability, or emotional problem according to a survey by the National Center for Health Statistics. The 1988 National Health Interview Survey of Child Health found such disorders among the most prevalent chronic conditions of childhood and adolescence, with a total of 10.7 million children affected. By the teen years, one in four children had experienced one of these disorders and, among male teenagers, almost three in 10 have been affected.

A report on the survey *Developmental, Learning and Emotional Problems: Health of Our Nation's Children, United States, 1988,* states that 4 percent of all children 17 years of age and under (2.5 million) had delays in growth or development; 6.5 percent among children aged 3–17, 3.4 million (6.5 percent) had learning disabilities and 7 million (13.4 percent) have had an emotional or behavioral problem that lasted three months or more or required psychological treatment.

About half of the children with a developmental delay had received treatment or counseling. More than three fourths of those with learning disabilities or emotional problems had received treatment or counseling, according to the parents reporting in the survey. Parents who reported that their child had a learning, developmental or emotional disorder were asked whether the condition made it necessary for the child to attend special classes, or a special school, or get special help at school. About a quarter of children with delays in growth or development and those reported to have emotional or behavior problems received special educational help. About 70 percent of those with learning disabilities received educational assistance for their disabilities.

In relation to family structure, young people from single-parent families or stepfamilies were two to three times more likely to have had emotional or behavior problems than those from two-parent homes. The prevalence of childhood emotional and behavioral problems showed significant variation across family income groups and minority populations with children from less advantaged backgrounds standing a somewhat greater chance of exhibiting such problems. Black and Hispanic parents were less likely than White non-Hispanic parents to report their children's developmental delays or emotional problems, suggesting that emotional and behavioral problems may be underreported by minority parents, when the data from this nationwide household interview survey are compared to data from other sources. Teacher reports and school records, for example, suggest that minority children are over-represented among special education and remedial instruction classes.

The 1988 National Health Interview Survey of Child Health was a survey of 17,100 children 17 years of age and under, residing in the home, and was based on interviews with an informed adult member of the family, usually the mother.

Socioeconomic Status and Survival from Soft-Tissue Sarcomas: A Population-Based Study in Northern Italy

Giovannino Ciccone, MD, Corrado Magnani, MD, Luisa Delsedime, MD, and Paolo Vineis, MD

ABSTRACT

Background and *Purpose:* Differential prognosis among cancer patients according to socioeconomic status (SES) has been reported. We analyzed survival from soft tissue sarcomas (STS) according to different SES indicators.

Methods: We followed up all the adult patients with a new diagnosis of STS occurring between 1.1.1981 and 31.12.1983 in an area of Northern Italy (N = 86).

Results: The overall three-year survival rate was 57 percent. After adjustment for confounders, both low education and blue collar jobs were negatively associated with survival.

Conclusions: The results suggest that patients of low SES have a poorer prognosis for STS. (*Am J Public Health* 1991;81:747–749)

Introduction

The five-year relative survival rates from soft-tissue sarcomas (STS) were about 60 percent in the United States in 1979–84.[1] Several studies have described the clinical and pathological determinants of survival from STS.[2–5]

In recent years, considerable attention has been paid to differential prognosis among cancer patients according to socioeconomic status (SES), particularly for breast and colon cancer.[6–9]

Differences in survival are interpreted as related to earlier access to diagnosis and therapy of higher social class patients.

We are not aware of previous investigations of the role of socioeconomic factors as predictors of survival among STS patients. The present investigation is based on the follow-up of all patients with a new diagnosis of STS among residents of a geographic area of Northwestern Italy.

Methods

A population-based case-control study of STS in the provinces of Novara, Vercelli, and Alessandria in Northwestern Italy was carried out between January 1, 1981 and December 31, 1983 among residents of 20 or more years of age to investigate the role of exposure to phenoxy herbicides in the etiology of STS.[10] Eighty-six subjects were enrolled, after histologic confirmation of the diagnosis by two independent pathologists.[10] The vital status and cause of death of all 86 subjects were ascertained during 1987 through correspondence with the municipalities where they resided at the time of diagnosis. The median follow-up duration was 38 months (mean 34.5; range 0–70).

In 1988 a subset of slides (n = 58) was reviewed by a different group of pathologists to evaluate each case according to a histopathological grading classification proposed by French authors.[3,4]

Within the case-control study, 18 of the 86 original cases could not be interviewed. Details on the questionnaire and the procedures involved are given elsewhere.[10] The following variables were analyzed as potential predictors of survival: age, sex, marital status, education, smoking habits, occupation, exposure to phenoxy herbicides, type of hospital of diagnosis (large public hospital vs small or private hospital), and site of origin, histotype, and histopathological grading of the sarcoma.

The analyses were performed using SAS programs.[11,12] Estimates of survival were obtained using the Kaplan-Meier product-limit method[13]; the statistical significance of the difference between survival curves was evaluated through the log rank test.[14] A multivariate analysis was performed including different SES indicators and other covariates; the Cox proportional hazards model was used.[15] Proportionality of risk over time was assessed for each variable introduced in the models through the plots of the log (−log) of the survival distribution function on the log of time.

*Each model includes also sex, age, and histopathological grading.

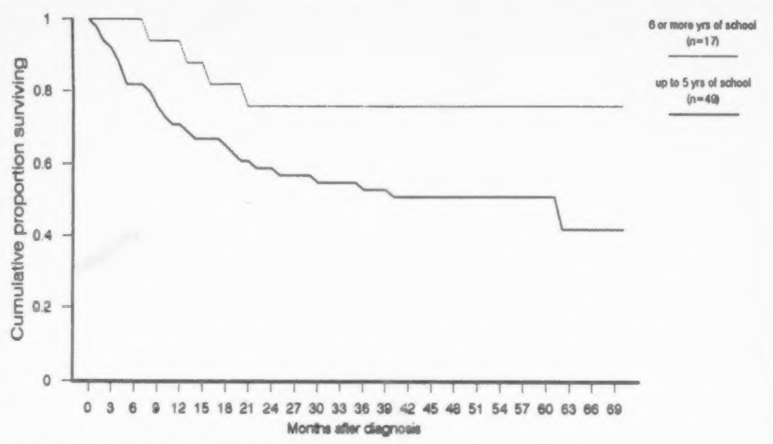

FIGURE 1—Survival from STS by Education

Results

The overall proportion of patients alive three years after a diagnosis of sarcoma of soft tissues was 57 percent.

The Appendix shows the distribution of the patients by site of the tumor, histology, and grading, according to vital status at the end of follow-up. Only two-thirds of cases could be reviewed for histopathologic grading: there is evidence that such classification is likely to be an important prognostic factor for STS.

Table 1 reports the distribution of several characteristics of the patients by vital status at the end of follow-up.

By univariate analysis, the less educated patients and unskilled workers (manual workers or farmers vs others) had poorer prognoses. Figure 1 shows the difference in the proportion surviving according to education. A similar pattern appears comparing survival experiences according to the main occupation.

To take into account the strong association between low education and unskilled jobs and the role played by other covariates in influencing survival, a multivariate analysis was performed, fitting three models. In all models estimates of different SES indicators were adjusted for sex, age, and histopathologic grading. Table 2 shows that low education is negatively related to survival; among blue collar workers, a poorer prognosis is evident for manual workers in industry but not for farmers.

Discussion

Differences in cancer survival according to socioeconomic status of the patient have already been observed for other cancers, both when comparing different categories of workers (i.e. blue vs white collar)[8] and when comparing different ethnic groups.[9] The differences seem to affect particularly breast and colorectal cancers which, at least in theory, could be more influenced by early diagnosis. In a study based on the Swedish Cancer Registry,[8] the following tentative interpretations for the observed social class differences were proposed: earlier detection in higher social class, with improvement of prognosis; earlier detection in higher social class, without improvement of prognosis (lead time bias); host factors, associated with social class, which influence the response to treatment; biological properties of the tumors arising in different social classes.

There is no evidence in favor of host factors or biologic differences in the tumors. Early detection seems to be more reasonable, but it is difficult to disentangle pure "lead time" (i.e. earlier diagnosis without real improvement of survival) and effectiveness of treatment.

Apart from histopathologic grading, only socioeconomic indicators showed an association with survival rates, with patients of low socioeconomic groups showing a worse prognosis. This observation does not rule out a more complex interpretation involving other factors not considered in the present analysis. Although our findings are based on a relatively small number of cases, they cannot be easily explained by bias, since the follow-up was successful for 100 percent of the 86 patients; SES was determined on *a priori* categorization of education and occupation; follow-up procedures were completely blind as to the predictors used in the analyses; differences in survival between patients of different socioeconomic groups were not confounded by age, sex, or tumor grading.

Unfortunately, we had incomplete information about clinical variables, such as stage of cancer at first symptoms or signs or type of treatment. Separate analysis according to histologic type is of little help because there are too few cases in each group. Although they show different probabilities of survival, ranging from zero through almost 100 percent, there is no obvious grouping of histologic types which could make a comparison between social classes easier. The histopathologic grading, a good prognostic factor, was available for only two-thirds of our cases.

The present report, like those cited earlier, suggests the existence of inequalities in health, associated with patient socioeconomic status. More analytical studies to control from a pure "lead time" effect are in order. ☐

APPENDIX—Proportion of Decreased Patients at the End of Follow-up by Site, Histotype,* and Grading of the Soft-tissue Sarcoma.

	Deceased n	Total n
Site of the tumor		
Head and neck	3	8

Pesticide Poisoning Surveillance through Regional Poison Control Centers

Debra Kay Olson, RN, MPH, Lynn Sax, Paul Gunderson, PhD, and Leo Sioris, PharmD

ABSTRACT

The purpose of this study is to describe pesticide exposure in the population of callers to Minnesota Regional Poison Centers. Case files from 1988 reporting pesticide exposure to humans were identified in cooperation with the Minnesota Center for Health Statistics. Data analysis was conducted by computer using SAS statistical package.

Of the 1,428 case files indicating pesticide as the primary substance of exposure to Minnesota residents, a mean age of 5 years (range, one month to 85 years) was identified; 50 percent of all cases were below age 3 years. Males accounted for 1.3 times as many cases as females.

Insecticide was identified in the largest percentage of case files (74 percent) followed by herbicide (12 percent), rodenticide (11 percent) and fungicide-nonmedicinal (3 percent). Ingestion was the most common route of exposure; 85 percent of all calls originated from a residence.

While insecticides are still the most common types of pesticide call, herbicide has surpassed insecticide in production and sales in the US. In this study, herbicide type exposure calls present a much different picture than other pesticide types.

The usefulness of poison control centers for examination of pesticide poisoning is explored. Since reporting occurs coincidental with the exposure and its associated symptoms, each pesticide poisoning report could potentially serve as a true sentinel health event. (*Am J Public Health.* 1991;81:750–753)

Introduction

Pesticides represent a large group of chemicals which in general usage are described in terms of the organism they are intended to kill.[1–3] As the use of these chemicals has unfolded, some disquieting phenomena have been observed. A 1984–85 Nebraska study found an annual incidence rate of pesticide-related illness of 1.35 cases per 10,000 population.[4] Lymphoma and leukemia have been associated with higher death rates among Midwestern farmers in regions of high pesticide use[5,6] and Reeves[7] reported 15 children ages 2 to 17 years as having blood dyscrasias developed shortly after inhalation exposure to household insecticides. Pesticides account for a small but important number of acute human poisonings, particularly in a state with substantial use of pesticides in both rural and urban areas, such as Minnesota.[8,9]

Methods

The purpose of this study was to describe pesticide exposure in the 1988 population of callers to Minnesota Regional Poison Control Centers located at Hennepin County Medical Center and St. Paul-Ramsey Medical Center. Centers document exposure data utilizing the Cooperative Poison Center Report Form as designed by the American Association of Poison Control Centers (AAPCC). Data from these report forms were processed through each Center's computer system and sent to the AAPCC's national data collection project in Denver, Colorado. Data tapes containing all of the 1988 data for each Regional Center were then returned to the Minnesota Center for Health Statistics (MCHS) for collation, formatting, and analysis.

In cooperation with the MCHS all Minnesota resident case files from 1988 reporting pesticide exposure to humans were identified. All calls regarding human contact with a chemical coded by the AAPCC to be a herbicide, insecticide, rodenticide, or fungicide (nonmedicinal) were selected. A total of 2,209 calls were classified by the AAPCC system as pesticide exposure calls for Minnesota in 1988, 4.3 percent of all human exposure calls to Minnesota. Of these calls, 1,428 identified pesticides as the primary substance and 31 call files identified pesticides as a secondary substance of human exposure to Minnesota residents. The remaining 750 calls were incomplete data files or lacked the designation as a Minnesota resident, thus were not available for secondary analysis.

The following descriptive analysis applies to the 1,428 call files indicating pesticide as the primary substance of exposure to Minnesota residents in 1988. These data were derived from self-reported information. The use of poison control caller files imposes the following limitations upon the data: an unknown number of pesticide exposure events may occur for which no call was made; voluntary reporting of data via telephone is verified only by

TABLE 1—Insecticide Exposure Calls by Primary Substance Category, Minnesota, 1988

Substance	Frequency	Percent
Organophosphate only	220	20.8
Organophosphate in combination with carbamate	71	6.7
Organophosphate in combination with chlorinated hydrocarbon	15	1.4
Organophosphate in combination with other pesticide	7	0.7
Chlorinated hydrocarbon only	116	10.9
Chlorinated hydrocarbon in combination with other pesticide	6	0.6
Borates/boric acid (pesticide only)	29	2.7
Carbamate only	189	17.8
Carbamate in combination with other pesticide	6	0.6
Veterinary pesticides (for pets - flea collars, etc.)	49	4.6
Piperonyl butoxide and pyrethrins in combination (without organophosphate or carbamate)	80	7.5
Pyrethrins only (alone)	59	5.6
Rotenone	5	0.5
Piperonyl butoxide only (alone)	2	0.2
Insect repellants (excluding capsicum containing products)	163	15.4
Other	29	2.7
Unknown	14	1.3
Total	1060	100.0

follow-up phone calls by poison center specialists; data acquired by telephone are limited to those who have access to telephones and knowledge of the poison center service; and by AAPCC definition exposure relates only to suspected contact with any substance(s) which, when inhaled, ingested, applied to, injected into, or developed within the body, may cause damage to structure or disturbance of function to living tissue. An actual poisoning event can only be verified through review of medical outcome.

Results

Insecticide was identified in the largest percentage of case files for Minnesota (1,060 cases, 74 percent) followed by herbicide (168 cases, 12 percent), rodenticide (155 cases, 11 percent), and fungicide-nonmedicinal (45 cases, 3 percent). Of the insecticide cases, those containing organophosphates (alone or in combination) were reported most often (Table 1).

Carbamates were reported in 10 cases of fungicide exposure. Of the remaining fungicide cases, 19 were associated with phthalimide, three with non-mercurial fungicides, and 13 unknown/other.

Herbicide cases were most frequently associated with 2,4-D (2,4-dichlorophenoxyacetic acid) or 2,4,5-T (2,4,5-trichlorophenoxyacetic acid) (78 cases, 46 percent) and triazine herbicides (10 cases, 6 percent). Diquat was associated with 13 cases, carbamate with four cases, and other or unknown with 63 cases.

Rodenticide exposure calls were primarily associated with anticoagulant types (128 cases, 83 percent). Strychnine was associated with three rodenticide exposure calls and the remaining 24 rodenticide cases were other/unknown.

Of the 1,428 cases, a mean age of 5 years (range, one month to 85 years) was identified; 50 percent of all calls were regarding children under the age of 3 years (Table 2). The 13–17 years category accounted for the least number of cases overall. The 18+ years old category accounted for 53 percent of all herbicide-related calls.

Male to female ratio was 1.3:1 ± 0.2 for all pesticide-related calls, as well as for individual pesticide types, except herbicides, where males represented twice the number of cases as females.

Ninety-nine percent of all pesticide calls were reported as unintentional poisonings. General calls (not otherwise specified) accounted for 94 percent (1,323 calls) of the unintentional calls while occupational-related exposure made up 4 percent (62 calls).

Calls originating from a residence accounted for 85 percent of all pesticide poisoning calls. Health care facilities accounted for 11 percent and work place for 3 percent.

Ingestion was the most common route of exposure overall, and for each pesticide type (60 percent), except herbicide, where ingestion accounted for 39 percent and dermal exposure accounted for 45 percent of calls.

Pesticide exposure calls by two-hour interval present a bimodal distribution peaking between 10:00 am and 11:00 am (190 calls, 13 percent) and 6:00 pm and 7:00 pm (251 calls, 18 percent). Calls by two-hour interval by pesticide type show a similar bimodal distribution for each specific type of pesticide. The largest percent of pesticide-related calls occur in the months of May (16 percent), July (15 percent), and August (13 percent) (Table 3).

Thirty-three percent of the calls (468 calls) were documented as symptomatic. Two hundred eighty-eight of these were classified as symptomatic related to the pesticide exposure. By pesticide type, rodenticide calls reported the least number (3 percent) of calls as symptomatic related to the exposure.

Ninety-nine percent of all calls were associated with acute exposures. The majority of calls were managed at a non-health care facility (86 percent) while 12 percent were either managed at (107 calls) or referred to (69 calls) a health care facility. More fungicide cases (93 percent) were managed at a non-health care facility (e.g. managed at home) than any other pesticide type.

Discussion

Since 1986, pesticides have accounted for approximately 4.3 percent of all human exposure calls reported to Minnesota Regional Poison Centers. This is consistent with the percent of calls associated with pesticides nationally as reported by the AAPCC.[8] As such, the state data reported here represent but a small portion of a much larger national picture.

Over the past 20 years in the US, organochlorine insecticides have lost favor because of their long-term health effects and persistence in the environment and have been surpassed in use by organophosphates and carbamates.[10] Acute toxicity related to organophosphate pesticides is usually of rapid onset thus symptoms can be more readily associated with acute exposure to this pesticide type. It is thus not unreasonable that exposure to organophosphate insecticides make up the greatest percent of calls (22 percent) in this study. This is also consistent with a Nebraska study where 25 percent of the emergency room visits and hospitaliza-

tions for pesticide-related illness during the 1984–85 crop season were due to organophosphates.[4]

In our study herbicide type exposure calls present a much different picture than other pesticide types. They are typically associated with the adult (18+ years) male experiencing a dermal exposure. With the growing use of herbicides both in agricultural (175 percent increase from 25 years ago[2]) and urban settings the percentage of calls received (0.4 percent of all human exposure calls since 1985) in comparison to exposure potential appears low.[11–14]

Looking at the adult environments of work place (six calls) and type of exposure as occupational (18 calls), the difference in exposure for herbicides by age is not explained. It is still general unintentional residence exposures that account for the majority of herbicide calls in this study. Why this overrepresentation of adults for herbicide exposure calls occurs is an area for further research.

With 50 percent of all calls, examined in this study, reporting pesticide exposure to children under the age of three years, concern arises over long-term effects to this population group. Several authors have explored the long-term effects of such exposures on children.[2,15,16]

Chronic exposure to fungicides has been reported by Moses[2] as posing the greatest risk of cancer as compared to other pesticide types. Thus, while representing only 3 percent of the calls in this study, the cumulative effects of such exposures may have far greater implications.

Blanc and Olson[17] suggest that poison centers are ideally suited to occupational disease surveillance as used for early detection of disease, for timely identification of individual cases, and temporal trends. In this sense, each poison center report could potentially serve as a sentinel health event. Sentinel health events refer to a preventable disease, disability, or untimely death whose occurrence serves as a warning signal that the quality of preventive and/or therapeutic medical care may need to be improved.[18,19]

Acute pesticide poisoning reports, as used in this study, would meet the criteria used by Blanc, *et al*,[17,20] in their investigation of the usefulness of poison center data. Those exposures to pesticides with rapid onset of symptoms, such as in the case of organophosphates, are ideally suited for surveillance through such a system. Reporting occurs coincidental with the exposure and its associated symptoms, and there are no delays as in the case of retrospective surveys. In this sense, each pesticide poisoning report could potentially serve as a true sentinel health event for the state. ☐

Acknowledgments

The initial development of the statewide data system was funded by the Minnesota Regional Poison Center and the Medical Education Research Foundation at St. Paul-Ramsey Medical Center in cooperation with the Minnesota Department of Health, Minnesota Center for Health Statistics. Additional support was provided by the University of Minnesota, School of Public Health, Public Health Nursing and BRSG S 07 RR 055448, Biomedical Research Support Grant Program, Division of Research Resources, and National Institutes of Health grant. Analysis of pesticide poisoning exposure data was funded in part by the National Institute for Occupational Safety and Health, Occupational Health Nursing Research Training grant, Midwest Center for Occupational Health and Safety, and the Minnesota Department of Health.

Lead Exposure in Outdoor Firearm Instructors

Ram K. Tripathi, PhD, Peter C. Sherertz, PhD, Gerald C. Llewellyn, PhD, and Carl W. Armstrong, MD

ABSTRACT

This study was conducted to determine lead exposure of firearm instructors at an outdoor firing range, while cadets were firing nonjacketed and jacketed lead ammunitions. The breathing zone air for lead exceeded the Occupational Safety and Health Administration standard of 50 μg/m^3 for two instructors during firing exercises using nonjacketed bullets. The use of totally copper-jacketed bullets reduced the breathing zone lead levels by 92 percent for instructor #1 and by 96 percent for instructor #2; subsequent blood lead levels showed a significant decline in both instructors. (*Am J Public Health.* 1991;81:753–755)

Introduction

Lead poisoning from exposure to airborne lead in indoor firing ranges is an occupational disease of public health concern. Several studies of occupational lead toxicity have been documented at indoor firing ranges.[1–7] The major route of absorption for lead in firing ranges is through inhalation of lead dust and fumes. Inadequate ventilation and lack of personal protective equipment use by instructors may result in lead toxicity.

Instructors assigned to firing ranges are likely to have higher exposures because they may spend significant time in that environment. Several occupational studies have suggested that exposure to lead may be a health risk for users of indoor firing ranges.[8–10] However, the extent of this risk among firearm instructors at outdoor firing ranges has not been documented. This study had two objectives: to evaluate the health risks to instructors from airborne lead exposure from nonjacketed, lead bullets; and to document the reduction or elimination of this risk by using totally copper-jacketed lead ammunition.

Methods

Two instructors, not involved in firing, were studied from June 17 to Septem-

	Blood Lead Level (μmol/L)	
Dates	Instructor #1	Instructor #2
Nonjacketed bullets		
June 18, 1987	1.01	0.48
June 19, 1987	1.30	0.77
July 7, 1987	1.21	0.77
Mean	1.16	0.68
Copper-jacketed bullets		
September 4, 1987	1.06	0.63

[a] Pre-exposure baseline blood lead levels collected on June 17, 1987, in μmol/L, for instructors 1 and 2 were 1.01 and 0.48, respectively.

ber 4, 1987. Cadets fired a total of 950, 1,539, 3,000 nonjacketed, and 2,160 jacketed bullets on June 18, 19, July 7, and September 4, 1987, respectively. The total number of cadets involved in firing were seven, seven, six, and six on June 18, 19, July 7, and September 4, 1987, respectively. A description of the covered outdoor range was reported previously.[11] Thirty-eight caliber police revolvers and conventional, nonjacketed lead bullets (.38 special caliber, manufactured by 3D Inv, Inc., Doniphan, NE) were used, as well as totally copper-jacketed lead bullets (.38 caliber special ammunition, Omark Industries, Lewiston, IA).

All background, general area, and breathing zone air samples were collected on cellulose ester filters following standard procedures.[11] Background and general area samples were collected within the perimeter of the range one hour before and during firing, respectively. The breathing zone samples were collected near the chest and face of the instructors. All samples were analyzed by atomic absorption spectrophotometry.[12]

Prior to firing activities, individual interviews were conducted and questionnaires administered to obtain information on demographic and other potential sources of lead exposure. Venous blood was drawn to obtain baseline values for blood lead on June 17, 1987. A second questionnaire was administered on July 7, 1987 to assess any symptoms of lead toxicity and to ascertain any other recent potential sources of lead exposure. A third questionnaire was administered on September 4, 1987 after the study was completed. Blood was drawn on June 18, 19, July 7, and September 4, 1987 after each firing activity. All samples were analyzed according to the method of Brodie and Routh (1984)[13] by the National Health Laboratory, Vienna, VA.

Results

The mean concentration of lead in μg/m³ for June 18, 19 and July 7, 1987 was 0.8 (range 0.3–1.2) in the background area air samples and 87 (range 3.8–299) in general area air samples during the firing. The mean concentrations of lead for background and general area air samples during use of copper-jacketed bullets for September 4, 1987 were 0.5 μg/m³ and 9.5 μg/m³, respectively, as previously reported.[14] Use of copper-jacketed ammunition resulted in an 89 percent reduction in lead levels in general area air samples.

The instructors were exposed to different personal breathing zone air lead concentrations on two sampling dates (Table 1). The mean breathing zone lead level with nonjacketed bullets was 67.1 μg/m³ for instructor #1, and 211.1 μg/m³ for instructor #2. The mean breathing zone lead levels during use of the jacketed bullets for instructors 1 and 2 were 5.4 μg/m³ and 8.7 μg/m³, respectively. This resulted in a reduction of 92 percent for instructor #1 and 96 percent for instructor #2.

After use of nonjacketed lead bullets, the mean blood lead level was 1.16 μmol/L for instructor #1, and 0.68 μmol/L for instructor #2 (Table 2). None of these values exceeded the current Occupational Safety and Health Administration (OSHA) return standard of 1.93 μmol/L (40 μg/dl) or removal standard of 2.4 μmol/L (50 μg/dl).[15] After the use of copper-jacketed lead bullets, blood lead levels for instructors 1 and 2 were 1.06 μmol/L and 0.63 μmol/L, respectively.

Discussion

All personal breathing zone lead level samples collected on June 19 and July 7 were above the current OSHA standard of 50 μg/m³.[15] The majority of air lead levels for general area air samples and all breathing zone samples taken while using nonjacketed lead bullets were above the action level of 30 μg/m³, for an eight-hour, time-weighted average (TWA).

The instructor blood lead levels measured during the nonjacketed lead bullet study indicated increases in blood lead concentrations. Blood lead levels reflect very recent lead exposures and are influenced by inhalation and ingestion. They may not reflect the total body burden of lead. Several studies have suggested that inhalation of air containing 1 μg/m³ will increase the blood lead concentrations of an adult by about 0.048 μmol/L when air lead concentrations range from 1 to 5 μg/m³.[16–18] Public health officials, as well as range owners, should be aware of design problems and work habits in outdoor ranges, especially covered ranges where exposures of instructors and other users may occur.

While no definite case of lead toxicity was encountered herein, the instructors experienced increased levels of lead in their blood while cadets were firing nonjacketed lead bullets. Interviews conducted with instructors revealed that the firearm instructors commonly supervise new cadets two to three times per month. This intermittent supervision probably has prevented serious lead toxicity in these instructors. If other covered outdoor firing ranges have air lead levels similar to those found in this study, frequent users would have an increased health risk from the lead exposure based on the present data.

The present study emphasizes a potential health risk of exposure to lead for firearm instructors in this type of outdoor firing range. Such levels were attributed to the firing of conventional, nonjacketed, lead bullets by the cadets. Inadequate ventilation may have contributed to the elevated lead levels found in the general area air samples and personal samples of the instructors. This potential health risk was substantially reduced by using totally copper-jacketed ammunition. The use of jacketed ammunition, as shown in this study and other studies, was very effective in reducing the air lead levels in general area and personal breathing zone air samples.[19–22] Even with such short-time exposures, instructors showed elevated blood lead levels. Remedies to such exposures not only include the use of jacketed ammunition but the adequate ventilation of the facility. □

Acknowledgments

The authors gratefully acknowledge the assistance of S.L. Ramsey for collecting blood samples; the Virginia State Police Academy for allowing us to conduct the study; the instructors who participated in this study; and Barbara Spain for typing the manuscript. Appreciation is extended to Grayson B. Miller, Jr, MD, Office of Epidemiology, Virginia Department of Health, as well as the Department of General Services, Virginia Division of Consolidated Laboratory Services for the assistance provided. Soft Plastic Bread Packaging: Lead Content and Reuse by Families

Clifford Weisel, PhD, Michele Demak, MPH, Steven Marcus, MD, and Bernard D. Goldstein, MD

ABSTRACT

The presence of lead in labels painted on soft plastic bread packaging was evaluated. Lead was detected on the outside of 17 of 18 soft plastic bread bags that were analyzed, with an average of 26 ± 6 mg per bag with lead. Of 106 families questioned, 16 percent of respondents reported turning the bags inside out before reusing for food storage, thus putting food in contact with the lead paint. We estimate that a weak acid, such as vinegar, could readily leach 100 μg of lead from a painted plastic bag within 10 minutes. Further, lead and other metals painted on food packaging of any type becomes part of the municipal waste stream subject to incineration and to landfilling. The use of lead in packaging presents an unnecessary risk to public health. (*Am J Public Health.* 1991; 81:756–758)

Introduction

Low level effects of lead on intelligence and on behavior have been repetitively documented,[1-6] and a causal relation between low levels of lead and fetal malformations, adult hypertension, and auditory acuity has been suggested.[7-10] This recognition has led to efforts to diminish lead exposure, particularly from older homes containing indoor lead paint and from gasoline.

Lead and other metals are also present in colored plastics. However, only submicrogram/cm^2 amounts were extractable in acid or ethanol solutions when these are imbedded in the plastic itself.[11,12] Pigments used to decorate plastics sometimes included lead chromates[13] and if used on food wrappings the potential for transference to food exists.[14,15] While such painting is done on the outside of plastic food wrappings, the opportunity exists for the paint to come in contact with food, particularly if the soft plastic bag is reused. Additionally, the wrappings eventually are included in municipal solid waste disposal facilities and, therefore, the added lead is transferred to the environment.

Methods

Lead Analysis

We purchased 18 breads representing 14 different national brands from three different national chain supermarkets in three New Jersey towns about 80 miles apart: Westfield; Highland Park; and Woodbury. The breads included: white bread, whole wheat, bagels, and pita. A 50 or 200 cm^2 section of each wrapper, containing the printing, was removed, weighed, rinsed with distilled water, and placed in an acid washed beaker. Sections of clear plastic were also cut from several bags to serve as blanks. The total lead content was determined by either a hot or cold concentrated acid extraction. The hot acid extract consisted of 5 mL of nitric acid followed by heating at 250 °C until approximately 0.5 mL remained, then 5 mL HCl with heating until 0.5 mL remain. The cold acid extraction used 5 mL of HCl. The residue from each treatment was diluted to 25 mL with distilled water and analyzed using flame atomic absorption spectroscopy.

Survey Methods

A survey was designed to assess the extent to which soft plastic bread packages may be reused. We targeted families with young children, the subgroup of major concern for increased lead body burden. Two parent groups were surveyed by questionnaire in May and June of 1990. Fifty-three of 84 questionnaires were returned from the first group, and 53 of 90 from the second group (overall response rate 61 percent).

Most respondents are in their thirties, and are well-educated mothers of young children. They are the usual buyers of bread for their households, buying an average of two such packages per week.

Results

Lead was detected in the sections containing printing or designs on all but one of the soft plastic bread bags that were analyzed, but was not present in any of the clear sections of the bags (Table 1). The mean ± S.E. amount of lead for these bags with lead was 26 ± 6 mg. Incubation of the plastic wrappers in 5 percent acetic acid resulted in extraction of 6.8 percent of the lead pigment (mean of 4 studies) in 10 minutes and 10 percent in 60 minutes (mean of 6 studies).

Italian	ND	50	ND
Rye	0.9	50	0.9
White	7.9	40	6.3
White	22	95	39
Pita	2.8	50	1.1
White	29	75	44
Rolls	13	40	10

ND—not detected.

An average bag size of 2000 cm² was used to calculate the total lead content on the bags of white bread, 1000 cm² for the smaller bags.

Survey Results

Of the 106 respondents, 41 (39 percent) report reusing the packaging or bag from bread products. The reasons for doing so included: concern for the environment (34 families); convenience (24 families); and saving money (17 families). Food storage and/or packing lunch were the uses most often cited, with more than half of the "reusers" reporting these applications. These packages may be used on multiple occasions: eight families reused them at least three times.

Of the 41 reusers, 23 do so after turning the package inside out, and 17 of these families report using the bags while inside out for food storage. Thus 17 of the 106 respondents (16 percent) store food in contact with the painted label.

Preliminary analyses indicate no relationship between respondents' level of education and package reuse, although respondents who attended graduate or professional school are somewhat more likely to turn the bags inside out. Similarly, no obvious or significant relationship emerges for respondents who are full-time homemakers compared with those working outside the home. Anecdotal information suggests that the rationale for turning the bag inside out before reuse includes removal of bread crumbs that might become moldy, and drying the inside of the bag which picked up moisture from the bread. We were told of paint flaking from the inverted package onto stored food.

Discussion

The Environmental Protection Agency (EPA) estimates that 10 percent of municipal waste is incinerated, 10 percent recycled, and the remainder ends up in landfill.[16] The Food and Drug Administration (FDA) estimates that between 35 and 55 g of white bread and an additional 15 to 25 g of rolls and whole wheat bread are consumed daily across several age groups.[17] Assuming that each package of bread contains one pound and that 60 g of bread are consumed daily, 3.0×10^7 bread bags are disposed daily in the US. Assuming bread bags have an average lead content of 26 mg, 0.8 metric tons of lead would be added to the municipal waste stream daily. This lead could enter the environment as a result of incineration or leaching into groundwater from a landfill. Plastics are currently a prime candidate for recycling. The reduction of toxins is needed[16] to minimize exposure to workers involved in recycling and to increase potential uses of the final product.

EPA estimates that the daily baseline ingestion of lead from food, water, and beverages is between 32 and 40 µg.[17] Inhalation is estimated to give an additional exposure of 20 µg daily.[18] Based on our present findings, we conservatively estimate that a weak acid, such as vinegar, in contact with the pigment for as little as 10 minutes, could extract about 5 percent of the lead. For a 100 cm² surface, the size of a single slice of bread, this would produce an exposure of about 100 µg of lead.

Efforts are underway to reduce lead exposures through the removal of lead from gasoline, solder from cans, and, most importantly, from homes with deteriorated lead paints. However, our findings suggest that an additional source that is dependent upon the habits of individuals, and not measured by current procedures for food analysis, may need to be considered when estimating total lead exposure.

Although presenting an unnecessary risk to health which should be discontinued, we do not believe it likely that the use of inverted bread packaging to store or transport food presents an immediate threat to the health of family members necessitating an emergency response. However, obtaining blood free erythrocyte protoporphyrin or lead levels is a valuable part of the routine medical evaluation of all young children and is particularly important for high-risk groups.[18] Until this use of lead is prohibited, plastic packaging should not be turned inside out to store or transport food. ☐

Non-Hodgkin's Lymphoma in a Cohort of Vietnam Veterans

Thomas R. O'Brien, MD, MPH, Pierre Decouflé, ScD, and Coleen A. Boyle, PhD

ABSTRACT

We examined the incidence of non-Hodgkin's lymphoma (NHL) in a cohort of 18,313 United States Army veterans from the Vietnam era. Diagnoses were confirmed through a review of hospital records. Among veterans who had died after discharge or who had participated in a telephone interview (8,170 Vietnam veterans and 7,564 non-Vietnam veterans), seven Vietnam veterans and one non-Vietnam veteran had developed non-Hodgkin's lymphoma (p = 0.07). As none of the NHL cases had military job titles which suggest that they were occupationally exposed to herbicides while in Vietnam, the reasons for the excess are unclear. (*Am J Public Health.* 1991;81:758–760)

Introduction

Results of studies of occupational groups exposed to phenoxy herbicides have raised concerns that Vietnam veterans may have an increased risk of developing non-Hodgkin's lymphoma (NHL) because of possible exposure to the phenoxy herbicide Agent Orange, used in South Vietnam between 1966 and 1970.[1-3] These concerns have been heightened by reports of an increased risk of NHL among Vietnam veterans.[4,5] In the Centers for Disease Control Vietnam Experience Study (VES), the health of US Army Vietnam veterans was compared with that of Vietnam-era Army veterans who had not served in Vietnam. Although the VES was not designed to assess the risk of rare cancers among Vietnam veterans, the high level of concern about NHL led us to investigate and report the findings for NHL.

Methods

The study population consisted of 18,313 randomly selected, male US Army veterans (9,324 Vietnam veterans and 8,989 non-Vietnam veterans) who entered military service between January 1965 and December 1971. The VES included both mortality and health interview components, and the methods have been described in detail elsewhere.[6,7]

In this analysis, we combined mortality and interview data to determine the number of veterans with NHL in the cohort. Two hundred forty-six Vietnam veterans and 200 non-Vietnam veterans had died between separation from active duty and December 31, 1983, the closing date of the mortality component. A panel of physicians examined medical records of these veterans to determine the causes of death for each veteran.

In the interview component of the VES, we attempted to locate and contact all veterans not identified as deceased. Altogether, we interviewed 15,288 veterans (87.3 percent of eligible Vietnam veterans and 83.8 percent of non-Vietnam veterans) by telephone during 1985–86. If the veteran reported that he had been diagnosed with cancer, we asked him to describe the type of cancer that he had. To verify three self-reported cases of NHL and to identify other cases, we sought medical records for 47 veterans, including men who reported a malignant neoplasm of the lymphatic or hematopoietic tissues, men who reported a diagnosis of cancer of a site that could be NHL (e.g. lung, neck, stomach, lymph nodes), and men who reported a diagnosis of cancer but could not name a specific type or site. We could not

TABLE 1—Source, Diagnosis, Age at Diagnosis, Race, Period of Vietnam Service, Military Occupation, Military Region of Service, and Latency Period of Vietnam Veterans Diagnosed with Non-Hodgkin's Lymphoma, Vietnam Experience Study 1985–86

Source	Diagnosis[a]	Age at Diagnosis	Race	Vietnam Service	Military Occupation	Military Region	Months of "Latency"[b]
Interview	Diffuse mixed lymphocytic-histiocytic lymphoma	35	White	1968–69	Infantryman	III	172
Interview	Burkitt's lymphoma[c]	34	White	1968–69	Clerk Typist	III	148
interview	Poorly differentiated lymphocytic lymphoma	25	White	1968–70	Supply	I & III	75
Interview	Malignant lymphoma, large cell type	37	White	1966–67	Radar Maintenance	III	211
Mortality	Burkitt's lymphoma[d]	34	White	1968–69	Artilleryman	II & III	175
Mortality	Lymphoblastic lymphoma	24	White	1968–69	Infantryman	II	47
Mortality	Reticulum cell sarcoma	26	White	1968–69	Administrative Personnel Specialist	III	8

[a] On the basis of medical records.

[b] The "latent period" for NHL was taken as the time period between the beginning of the veteran's tour of duty in Vietnam and the initial medical contact that led to the diagnosis of NHL.

[c] On the basis of review of microscopic tissue specimen, diagnosis was malignant lymphoma (diffuse, small non-cleaved cell type) or Burkitt's lymphoma.

[d] On the basis of review of microscopic tissue specimen, diagnosis was poorly differentiated lymphoid malignancy with extensive sclerosis, consistent with acute lymphoblastic leukemia.

obtain medical records for six of the 47 veterans; none of the six had reported a lymphatic or hematopoietic cancer during the interviews. We made final diagnoses on the basis of pathology reports found in the medical records or, when no pathology report was available, the preponderance of evidence from the medical records. Pathology records were available in 31 of 41 (75.6 percent) of these medical records.

For analytic purposes, we divided the number of veterans with NHL (ascertained through either the mortality component or the interview) in each cohort by the sum of the number of veterans who had died and the number of veterans who had been interviewed (8,170 Vietnam veterans and 7,564 non-Vietnam veterans).

Results

We confirmed that all three veterans who had reported a history of NHL during the interview had been so diagnosed. A fourth veteran who, in the interview, had not specified the type of cancer had also been diagnosed with NHL. All four of these men were Vietnam veterans (Table 1). In the mortality study, three Vietnam veterans and one non-Vietnam veteran were found to have NHL. In total, seven Vietnam veterans and one non-Vietnam veteran were diagnosed with some type of NHL ($p = 0.07$, Fisher exact test (two-tailed)). On the basis of published age-specific cancer incidence data,[8] about 3.9 cases of NHL would have been expected among Vietnam veterans ($p = 0.10$, Poisson) and about 3.5 cases would have been expected among non-Vietnam veterans ($p = 0.14$, Poisson).

All of the Vietnam veterans with NHL had begun their tour in Vietnam from 1966 to 1968. The men had served in a variety of military occupations, and no specific occupation predominated. Regarding pathology, two Vietnam veterans were diagnosed as having Burkitt's lymphoma. On further pathologic review, one case was reported as possibly Burkitt's lymphoma, and the second was reported as acute lymphoblastic leukemia (Table 1).

The "latency period" was short for two Vietnam veterans (Table 1). One veteran first developed NHL eight months after arriving in Vietnam and a second Vietnam veteran had a "latency period" of 47 months.

Discussion

Although these results suggest an increased risk of NHL among Vietnam veterans, our findings should be interpreted with caution. The number of cases is small and, on review, one of the Vietnam veterans may have had lymphocytic leukemia rather than NHL. (These diseases are, however, closely related.[9]) The time period between the beginning of the veteran's tour of duty in Vietnam and the diagnosis of NHL should also be considered when interpreting these data, as the "latent period" for some of the cases presented here is much shorter than the usual period for environmentally caused cancers.[10]

The collective evidence for an unusual risk of NHL among Vietnam veterans is inconsistent. Two other studies have shown that Vietnam veterans may be at increased risk of NHL. Increased mortality from NHL was seen in a large study of US Marine Corps Vietnam veterans (proportionate mortality ratio (PMR) = 2.10; 95% confidence interval = 1.17–3.79), although the same investigators found a deficit of deaths from NHL in US Army veterans (PMR = 0.81; 95% CI = 0.63–1.04).[4] An elevated risk of NHL in Vietnam veterans was also reported in a large population-based case-control study (Odds ratio = 1.47; 95% CI = 1.09–1.97).[5] In contrast, a case-control study using subjects from Veterans Administration hospitals found a modest negative association between Vietnam service and NHL (OR = 0.72; 95% CI = 0.56–0.92).[11]

We could only indirectly assess possible exposure of these veterans to Agent Orange while in Vietnam. Although most of the men served in Vietnam during the time (1967–69) and area (III Corps) of heaviest spraying,[1] three of seven had non-combat military job titles that suggest they were unlikely to have been in contact with herbicides. Although the three men with combat-related job titles may have been exposed to Agent Orange, previous work suggests that, with the exception of men whose military occupation entailed handling herbicides, most US Army combat troops who served in Vietnam were not heavily exposed to dioxin.[12] Since no other factor in the Vietnam experience has been linked to the increased NHL risk, reasons for the excess found in this study and two other studies remain unclear. ☐

Acknowledgments

Linda Moyer, RN, obtained and abstracted medical records that were reviewed in this study. Dr. Elaine S. Jaffe reviewed microscopic tissue specimens. Sandra Tully and Sheila Allgood assisted with manuscript preparation.

Data for this study were gathered under an interagency agreement with the Veterans Administration.

Endemic Giardiasis and Municipal Water Supply

G. Graham Fraser, MB, ChB, MSc, and Kenneth R. Cooke, MB, ChB, PhD

ABSTRACT

To test the hypothesis that endemic giardiasis may be transmitted by unfiltered municipal water supplies, the incidence of laboratory-confirmed giardiasis was studied in a natural experiment due to the arrangement of the public water supply of Dunedin, New Zealand. The incidence rate ratio was 3.3 (90% CI = 1.1, 10.1) for the population receiving unfiltered (microstrained) water relative to that using sand filtered water. In a parallel case-control study of incident cases, the odds ratio for giardiasis and unfiltered (microstrained) water supply was 1.8 (90% CI = 0.5, 6.9). (*Am J Public Health.* 1991; 81:760–762)

Introduction

Epidemics of waterborne giardiasis originating from water supplies have been clearly associated with surface catchments, treatment systems that do not eliminate *Giardia* cysts, and downstream contamination of the reticulation system.[1–5] In contrast, there have been few tests of the hypothesis that surface catchment waters contribute to endemic giardiasis where treatment systems cannot eliminate cysts.[1,6,7]

Giardia cysts have only recently been isolated from water supplies in New Zealand. No substantive epidemics attributable to giardiasis have yet been documented. Many municipal supplies use surface waters and simple treatment methods that would not reliably filter or deactivate giardia cysts.[3,8]

The present study took advantage of a natural experiment—the divided water supply of the city of Dunedin, New Zealand—to test the hypothesis that endemic giardiasis might be transmitted by unfiltered municipal water supplies.

Methods

Dunedin (population 89,000) is supplied almost entirely by water from surface catchments. Most water is filtered by mechanical microstrainers (screen size 23 μm). Part of the city water is treated at a modern station (Mount Grand) using coagulation/flocculation and direct dual media filtration (anthracite and silica sand) that would normally be expected to remove any *Giardia* cysts present.[3,8] All water supplies are chlorinated and fluoridated.

Records of all laboratory-proven cases of giardiasis from persons residing within the Dunedin municipal water sup-

Microstrained	47	3.29	3.3 (1.1, 10.1)

*Primary household cases only. One case could not be classified, as domicile received a blend of both kinds of supply.
**Rate per 10,000 person-years.

TABLE 3—Giardiasis and Exposure to Microstrained Water: Case-Control Study

Exposed to Microstrained Water	Cases	Controls
Ever	19	53
Never	2	10
Odds Ratio (90% CI)	1.8 (0.5, 6.5)	

ply area were obtained from the two medical laboratories in the city for two periods (February to December 1986 and April 1987 to February 1988). Each record included age, sex, residential address, presence of *Giardia* or other pathogens, and the date of receipt of the fecal specimen. The laboratory diagnosis was made by direct microscopy following formalin-ethyl-acetate sedimentation and iodine staining. The denominators for rates were obtained from the 1986 Census of the usually resident populations of the respective water supply areas.[9]

A case-control study was also conducted using cases in the 1987–88 period. Controls were selected from the population referred for laboratory parasitology examination who had negative findings for giardiasis. Three controls were selected per case; cases and controls were matched for age, sex, and season of occurrence of infection. Cases and controls were classified blindly by city council water engineers according to whether their residences were "ever" exposed to microstrained water during the presumed period of infection (defined as seven days to four weeks before the receipt of the fecal specimen).[10]

Relative risks, odds ratios, and confidence limits were computed using the programs of Rothman and Boice.[11]

Results

Fifty primary household cases of giardiasis were diagnosed in the two study periods. Subsequent cases in a household were excluded from the analysis (13 cases). Four further cases were excluded through insufficient or absent information on domicile.

The incidence of laboratory-confirmed giardiasis was greatest in preschool children and in the 15–34 age group (Table 1). The incidence of laboratory-proven giardiasis for residents of the two water supply areas are given in Table 2. In the first study period, 28 of the 29 cases were residents in areas supplied by microstrained water; the remaining case was in an area traditionally supplied by a blend of the two supplies. In the second study period, 19 cases resided in the microstrained areas and two cases in areas that received the Mount Grand supply. The relative risk of laboratory-confirmed giardiasis for residents of areas supplied by microstrained water was estimated at 3.3 (one-tailed P = 0.04). The risk ratio was essentially unchanged following indirect standardization for age.

In the case-control study the odds ratio for exposure to microstrained water was 1.8 (90% CI = 0.5, 6.5) (Table 3).

Discussion

The present findings suggest that endemic giardiasis can originate from the municipal water supply. Both the incidence estimates and the case-control analysis indicate a greater risk of laboratory-diagnosed giardiasis among residents of areas whose supply was treated only by mechanical filtration and chlorination.

The study was small and of correspondingly weak statistical power. As it was limited to the analysis of laboratory reports, information on some possible confounding factors was not available. However, some potential confounders are either unlikely to have had a significant effect, or would have operated as negative confounders. Age differences were not sufficient to account for differences in rates observed. The area with low rates included the most mobile young adult population. The two population areas may have differed in physician practice styles in the investigation of gastrointestinal symptoms, but this should have been accounted for by the case-control study. As most workplaces are supplied by Mount Grand water, misclassification from consumption of cold water at work would be expected to bias the relative risk toward unity. A small proportion of the controls may have had giardiasis (due to the intermittent nature of *Giardia* excretion) but this would bias the odds ratio toward unity.

The consistency of our findings with those of other case-control and descriptive studies[1,6,7] strongly suggests that transmission of endemic giardiasis can occur via municipal water supplies that do not use filtration technology capable of removing *Giardia* cysts. ☐

The Microbiologic Quality of Drinking Water in North Carolina Migrant Labor Camps

Stephen Ciesielski, PhD, Thomas Handzel, BS, and Mark Sobsey, PhD

ABSTRACT

A two-year study of the microbiological quality of drinking water in 27 randomly selected North Carolina migrant labor camps yielded total and fecal coliform prevalences of 44 percent and 26 percent, respectively in 1988 and similar but higher prevalences in 1989. Preoccupancy testing by county sanitarians had found virtually no total coliform contamination. These findings suggest that a potential source of contamination existed and that current testing protocols which rely on preoccupancy testing may be inadequate. (*Am J Public Health.* 1991;81:762–764)

Introduction

Although migrant farm workers are known to have a high prevalence of enteric infections,[1–7] many of which are water-borne, the potability of drinking water used by migrants has received little attention. This report presents the results of a two-year study of the microbiological quality of drinking water in North Carolina migrant labor camps.

Methods

In 1988, a random sample of 21 migrant camps was selected from a pooled list of camps in eastern North Carolina. Water was also tested in six additional camps, which were part of a related study of the incidence of enteric parasites in migrant farm workers, and 10 control sites (nearby rural businesses and residences). In 1989, all 23 inhabited study camps from the previous year were retested, along with seven additional nonrandomly selected camps. In all camps in both years, water was tested by county health departments prior to occupancy, the results of which were obtained after field study was completed.

Water samples were collected from taps (without aerators) into sterile 1 liter sampling bottles, kept chilled and analyzed within 24 hours. Microbiological testing of 100 ml sample volumes for total and fecal coliforms and *E. coli* was done according to standard protocols using membrane filter methods.[8] Sites with initial positive tests were retested when possible.

Fisher's Exact Test (two-tailed) and Chi-square tests were employed in data analysis.

Results

1988 Results

The bacteriological results for water samples from the 27 camps and 10 control sites are summarized in Table 1; 12 (44 percent) were positive for total coliforms with counts ranging from 1–186 colony forming units (CFU). Eight of these sites were retested and all were positive again. Seven samples (26 percent) were also positive for fecal coliforms. Two of 10 samples were positive for *E. coli*. All 10 control sites were negative for total and fecal coliforms. The presence of latrines (as opposed to flush toilets) was associated with total coliform occurrence in water (p = 0.024; Fisher's Exact Test).

*Total Coliforms.
**Fecal Coliforms.

1989 Results

Fifteen of 30 camps (50 percent) had water samples positive for total coliforms, 11 (37 percent) for fecal coliforms, and four for *E. coli* (Table 2). Fifty-six percent of resampled camps had the same result as the previous year. In 1989, latrines were not significantly associated with coliforms, but there was an increasing prevalence of coliforms in water samples as a function of time of occupancy. When the results of the four successive samplings of water are grouped as two early samplings and two late samplings, the total coliform prevalence in the early and late groups is significantly different by Chi-square analysis ($p = 0.056$). Rainfall during the week previous to the last two sampling periods totaled 3.68 inches while totaling 0.78 inches for the week prior to the first two sampling periods.[9]

In 1988 only one and in 1989 none of the camps studied were positive for total coliforms on preoccupancy testing by local health departments.

Discussion

In the United States over one-half of the reported outbreaks of waterborne disease are due to fecally contaminated groundwater, most often resulting from overflow or seepage of on-site septic systems.[10] Migrant camps are often overcrowded so that the amount of human fecal wastes may overload the design capacity of on-site sanitary disposal systems. These septic systems may also have exceeded their expected life span. Furthermore, migrants probably excrete greater numbers of pathogens into the septic waste system. Enteric infections, especially parasites, are major health problems among migrants.[1–7] Diarrhea is reported to be 20 times more frequent among migrants than the urban poor.[4] Most intestinal parasites identified in the migrant population can be transmitted by fecally contaminated water[1,3,5,11] and enteric bacteria and viruses have a much greater capacity for waterborne transmission.[7] The concurrent study of the incidence of intestinal parasites in which some study camps were included, found a significant association ($p = .024$) between incidence and total coliforms.* In Florida an echovirus (type 22/23 complex) was isolated from water samples in a migrant camp during an outbreak of gastrointestinal illness.[12]

The surprisingly high prevalence of total and fecal coliforms in migrant labor camp drinking water is a matter of serious concern. According to the US Environmental Protection Agency, "the presence of fecal coliforms in drinking water indicates that an urgent public health problem exists."[14] New standards proposed by the EPA would require the state to be notified within 48 hours when any number of fecal coliforms are demonstrated.[13] The health hazards associated with unsafe drinking water in migrant camps were demonstrated in 1973, when the largest outbreak of typhoid fever in the US since 1939 resulted from the contamination of well water in a Florida migrant camp, preceded by repeatedly high coliform counts in the camp's water supply.[14]

North Carolina's migrant housing regulations require that water in migrant camps housing 13 or more workers be tested before occupancy for total coliforms.[15,16] The failure of pre-occupancy inspections to ensure adequate water quality during habitation probably results from the fact that if coliforms have entered the water system when the camp is occupied in late summer, results are negative the following June (after a nine-month vacancy) due to bacterial die-off and dilution and dispersion in ground water. This variation with usage is supported by the increase in coliform prevalence observed in 1989 with each round of sampling, which suggests that overload of on-site waste water treatment facilities may be a factor. Increasing rainfall in the early autumn may also play a role.

On the basis of these findings, it seems logical to suggest that current regulations be revised to include water quality testing both before and during the period of habitation, not only in North Carolina, but in all states in which migrants are served by ground water sources. Further study is needed to determine the factors responsible for the presence of coliforms in drinking water so that effective intervention can be initiated. ☐

Salmonella Egg Survey in Hawaii: Evidence for Routine Bacterial Surveillance

Myra R. Ching-Lee, MPH, Alan R. Katz, MD, MPH, David M. Sasaki, DVM, MPH, and Henri P. Minette, DrPH

ABSTRACT

One hundred and six dozen eggs, representing 12 brands, were purchased from Oahu supermarkets and cultured for *Salmonella* using standard FDA (Food and Drug Administration) microbiological techniques. Two enrichment incubation temperatures were used to improve culture sensitivity. Ten cartons (9.4 percent) of the 106 dozen samples had shells positive for *Salmonella*. Seven of the 10 were traced to a single egg processor. Inspection of the facility led to the discovery of malfunctioning equipment used in the egg washing and sanitation process. (*Am J Public Health*. 1991;81:764–766)

Introduction

Large outbreaks of human salmonellosis in the United States, related to egg products and cracked shell eggs, led to the passage of the Egg Products Act in 1970. This law required visual inspection of eggs for cracks as well as mandating pasteurization for all bulk egg products.[1,2] Although this legislation led to an initial decrease in egg-related *Salmonella* outbreaks, they have again begun to rise.[2–5]

Contamination of eggs with *Salmonella* can occur in several ways: egg shells may be contaminated by feces[6]; cleaning procedures may be improper[7]; the interior of the egg may be contaminated by the shell being cracked. Contamination may also be internal, prior to shell formation through transovarian transmission.[5,8] In 1989, an Oahu high school student, as part of a science project, cultured two dozen eggs from a supermarket in Honolulu for *Salmonella*. Nine of 24 eggs (37 percent) were culture positive. The high recovery rate prompted the Hawaii State Department of Health to conduct a more definitive prevalence survey for *Salmonella* among eggs for sale in Oahu supermarkets.

Methods

Eggs representing 12 available brands were collected once each week for an eight-week period from June 26 through August 19, 1989. The sampling unit was defined as a carton of 12 large grade A eggs. The carton closest to the aisle was chosen without opening it. Following collection, the eggs were immediately transported to the Hawaii State De-

*Media = Plating media used: BGA (Brilliant Green Agar); XLD (Xylose Lysine Desoxycholate).

partment of Agriculture (DOA) laboratory for testing. No eggs were damaged, cracked, or visibly soiled.

Of the 12 brands available for study, three were from US mainland producers and nine were locally produced. Fourteen dozen eggs were potentially available each week from each of the 12 brands, as two brands sold both white and brown eggs. Both white and brown eggs were sampled when available. Three brands on some weeks were not available at the designated supermarket locations. Unsuccessful attempts were made to locate these brands at other store locations. A total of 106 dozen eggs were sampled and cultured.

Isolation and identification of *Salmonella* from eggs were conducted using methodology from the US Food and Drug Administration,[9] with one variation. In addition to the recommended incubation temperature of 35 degrees Celsius (C) for samples in tetrathionate enrichment medium, a second incubation temperature (41 degrees C) was used.[10,11]

In order to avoid cross-contamination of samples, glassware was autoclaved prior to and between each use. Individual sterile pipettes and sterile gloves were used, and the pre-enrichment media were autoclaved.

The eggs from each dozen were separated into two flasks; one containing the shells and the other containing the magma (white and yolks). All samples were incubated for 18–24 hours in a lactose broth, pre-enrichment medium.[9]

Samples from each flask were then transferred to two flasks containing tetrathionate enrichment broth. One set of samples was incubated at 35 degrees C and the other at 41 degrees C.[10,11] After incubation for 24 hours, one loopful from each flask (magma and shell) was streaked onto plates of Xylose Lysine Desoxycholate Agar (XLD) and Brilliant Green Agar (BGA).[9] Isolates were serotyped using Centers for Disease Control methods.[12]

Results

Salmonellae were detected in 10 cartons (9.4 percent) of the 106 dozen eggs sampled. Positive samples were from shells only. *Salmonellae* were detected in samples from only three of the 12 brands examined. The brand with the highest weekly prevalence (6/8) was locally produced; the second highest (3/8) was a mainland brand; while the third highest (1/8) was a local brand.

Use of two enrichment incubation temperatures resulted in improved *Salmonellae* isolation rates. Three of the 10 dozen eggs testing positive came only from the enrichment medium incubated at 41 degrees C. One positive sample came only from the enrichment medium incubated at 35 degrees C. The remaining six dozen positive samples grew at both temperatures. Serotypes *braenderup, oranienburg, mbandaka, cerro, ohio, havana, montevideo,* and *livingstone* were detected (Table 1).

Discussion

An earlier egg survey done in Hawaii[13] as well as surveys conducted in New York,[14] Missouri,[15] British Columbia, [16] India,[17] and Saudi Arabia[18] demonstrated the prevalence of *Salmonella* on the surface of washed, commercially processed egg shells to be 0–2 percent. However, these surveys used only a single enrichment incubation temperature.

The use of two incubation temperatures for the enrichment medium increased the sensitivity for *Salmonella* detection in the present study. *Salmonella* would have gone undetected in three of the 10 dozen eggs had only the standard incubation temperature been used.

The US mainland brand eggs testing positive for *Salmonella* were traced to a USDA supervised plant in California. Upon inspection, no deficiencies were observed in this plant. The two brands of locally produced eggs were traced to one processor and a single farm. As a result of this study, the Hawaii State DOA inspected the processing plant. Equipment used in the egg washing and sanitizing process was found to malfunction. The company voluntarily agreed to cease operations until the deficiencies were corrected. The eggs were diverted to another facility for processing pending repair of the defective equipment. To date, the facility has not resumed operations as an egg processing plant. It is currently being used as a storage facility (personal communication DOA).

Recent reports of egg-associated salmonellosis have incriminated Grade A shell eggs that were considered to have been properly processed.[2–5,8] While transovarian transmission has also been implicated as a possible cause for the resurgence in egg-borne salmonellosis,[5,8] deficiencies in egg-processing procedures may be of more importance.

In Hawaii, the state DOA is the only state agency with regulatory authority over the egg industry. However, the scope of its activity is limited to the structural integrity of the eggs. Currently, there are no regulations that mandate active surveillance and monitoring of eggs for bacterial contamination. Our data indicate that visual inspection of eggs is not enough. Ongoing egg bacterial surveillance with improved laboratory methods, including the use of two enrichment incubation temperatures to increase *Salmonella* culture sensitivity, would allow for early detection of deficiencies in egg handling and processing, and could eliminate *Salmonella* egg contamination as a potential cause of disease in the community. ☐

Agricultural Machine-Related Deaths

John R. Etherton, MEA, John R. Myers, MSF, Roger C. Jensen, PhD, Julie C. Russell, PhD, and Richard W. Braddee, BA

ABSTRACT

Analysis of 1980-1985 death certificate data for the United States indicated that an average of 369 occupational deaths per year involved agricultural machinery as the external cause of death. Out of all agricultural machine-related deaths, tractors accounted for 69 percent. Over half of these tractor-related deaths were rollovers. There is a need for public health programs to affect greater use of rollover protective structures (ROPS) on farm tractors. (*Am J Public Health.* 1991;81:766–768)

Introduction

Fatalities among farm machine operators present a conspicuous injury target for public health action.[1–3] Farm tractors are known to be particularly deadly,[4–6] but prevention programs appear to be floundering.

As a first step toward the establishment of priorities for fatality prevention programs in agriculture, we decided to examine the National Traumatic Occupational Fatality (NTOF) data base maintained by the National Institute for Occupational Safety and Health (NIOSH).[7,8] Previous analysis of NTOF data for the years 1980-85 had shown that the Agriculture, Forestry, and Fishing industry had a fatality rate of 20.7 per 100,000 workers, a rate 2.6 times higher than the national average for all industries of 7.9 deaths per 100,000 workers.[7]

Methods

Death certificate data in NTOF were reviewed to identify persons killed while working with machines. Machine-related fatalities were identified by codes E919.0 to E919.9 according to ICD-9. Next, the type of machine involved in each machine-related fatality across all United States industries was ascertained by reviewing the description of the cause of death on the death certificate. All agricultural tractor-related fatalities were then categorized and compared by the Standard Industrial Classification (SIC) for the industry in which the incident occurred.[9] Age at death was determined for those fatalities associated with tractors, augers, hay balers, combines, and other agricultural machines.

TABLE 1—Machine-related Occupational Fatalities, All US Industries, 1980–85

Machine Type	Frequency*	Percent of Fatalities
Agricultural machines, E919.0	2216	43.8
Lifting machines, E919.2	1029	20.3
Mining, earth drilling machines, E919.1	467	9.2
Earthmoving, excavating machinery, E919.7	458	9.0
Other specified machinery, E919.8	441	8.7
Unspecified machinery, E919.9	237	4.7
Metalworking machinery, E919.3	88	1.7
Transmission machinery, E919.6	78	1.5
Woodworking machinery, E919.4	47	0.9
Total	5061	99.8**

*Values are based on the 90.6 percent of case records in the NTOF data file that have ICD codes.
**Sum differs from 100 due to rounding.

TABLE 2—Frequency of Agricultural Machine-Related Fatalities (E919.0), All US Industries, 1980–85

Agricultural Machine	Fatalities	Percent
Tractor	1523	69
Auger/elevator	61	3
Combine	53	2
Hay Baler	42	2
Brush hog/mower	40	2
Loader/skidder	37	2
Corn picker	26	1
27 other machines	108	5
Unspecified machine	326	15
Total	2216	101

*Sum differs from 100 due to rounding.

Results

The search of NTOF cases identified 5,061 machine-related fatalities coded E 919.0 to 919.9 (Table 1). Agricultural machines were involved in 2,216 deaths, an annual average of 369 deaths per year. The second ranking machine category on the list is lifting machines (cranes, forklifts, etc.) which averaged 170 fatalities annually, less than half that of agricultural machines.

The seven types of agricultural machines with greatest fatality frequency are listed individually in Table 2. Machines with a frequency less than 1 percent were combined into one category. The final category includes fatalities in which the type of machine was not specified on the death certificate. These data indicate that tractors are involved in the vast majority of agricultural machine-related fatalities. All other agricultural machines are involved in far fewer fatalities when compared to tractors.

Tractor overturns were the single most important event in fatalities involving tractor operators. Of the tractor-related fatalities in the NTOF data set, 52 percent were rollovers. Another 16 percent involved the victim being run over, such as instances in which an operator fell off the tractor and was run over. About 7 percent of the tractor-related fatalities were associated with the power-takeoff.

Farm tractors are used in many industries. For example, using farm tractors to pull cut timber in logging operations is considered to be a manufacturing industry activity. Of farm tractor-related fatalities, 59.3 percent occurred in the agriculture, forestry, and fishing industry, while manufacturing, services, and construction industries each contributed over 5 percent to the national death toll. Victims over 50 years old accounted for 62 percent of farm tractor-related fatalities, and victims over age 60 accounted for 44 percent of farm tractor-related fatalities.

Discussion

The findings reported here are similar to those reported in studies of farm fatalities in Wisconson[5] and Georgia.[6] All of these investigations found that tractor overturns accounted for the largest proportion of farm deaths (Wisconsin 52 percent; Georgia 76 percent; US 52 percent.)

Education, enforcement, and engineering control are often cited as the avenues for prevention of occupational injuries and fatalities. The mandatory education approach to farm tractor safety has not yet received sufficient emphasis. Some training is available through voluntary organizations such as the 4-H and Future Farmers of America. However such training is voluntary. It is unnecessary to pass a test, as is the case with obtaining a license to operate a motor vehicle, unless the tractor driver is age 14–16 and employed by someone not in the family.[10] For all other farm tractor drivers, no license of any kind is required. Furthermore there is no competency-based certification program for tractor operators.

The enforcement approach also has problems. In its annual appropriations bills for the Occupational Safety and Health Administration (OSHA) in the US Department of Labor, Congress has consistently attached a rider which denies OSHA the authority to inspect farms with fewer than 11 employees. This exempts 89 percent of US farms which may choose to comply or not comply with federal safety standards, free of an OSHA inspection. Unlike some consumer products, which may not be sold in the US if they do not meet regulations of the Consumer Product Safety Commission, the sale of farm machinery is not regulated for safety. Because most farm workers are not covered by OSHA enforcement, regulating farm machine safety at the point of sale has been suggested as a promising way to protect farm workers from machine hazards.

The engineering approach involves efforts at preventing rollovers, as well as protecting operators if a rollover does occur by fitting tractors with rollover protective structures (ROPS). Much effort has already gone into the design of ROPS for tractors, and industry-accepted voluntary standards call for the provision of ROPS on new tractors. OSHA has a requirement that employers must have ROPS on new tractors built since October 25, 1976. One of the difficulties encountered in this approach is the fact that farm tractors tend to be used for so many years that replacement of older tractors with newer, safer tractors is proceeding very slowly. There is also a problem with some farmers removing ROPS from new tractors. Considering all these factors, during the next 10 or 20 years it is unlikely that the percentage of tractors with ROPS will increase rapidly unless

some significant changes take place. Although engineering has provided the technology for preventing most fatalities due to tractor rollovers, it appears that voluntary implementation is very slow.

In Sweden a very significant reduction in tractor rollover fatalities has been brought about by requiring rollover protection on farm tractors.[11] Between 1961 and 1983, Sweden was able to drop its annual fatality rate for tractor overturning from 12 per 100,000 farmers to 1 per 100,000 farmers. This was accomplished through regulations introduced periodically between 1959 and 1981.

It will take cooperative action, including input from farmers, to develop creative prevention programs to solve this difficult problem. Education, enforcement, and engineering will work if they are supported by the common interest of a united agricultural public health community. Achieving this unity is a crucial goal for the 1990s. □

A Cross-sectional Study of Pulmonary Function in Autobody Repair Workers

David L. Parker, MD, MPH, Kirsten Waller, MD, MPH, Brenda Himrich, MS, Anita Martinez, MS, and Frank Martin, PhD

ABSTRACT

This study evaluated pulmonary function in workers from 39 autobody repair shops. Based on 152 White male workers with known smoking status, the mean percent predicted FEV_1, FVC, and FEV_1/FVC were 93.6, 96.8, and 96.6, respectively. Twenty-three percent of workers had a FEV_1/FVC ratio less than the fifth percentile. Isocyanate levels ranged from nondetectable to 0.06 parts per million (STEL = 0.02 ppm). No shop had an adequate respiratory protection program. We concluded that there was an increase in abnormal pulmonary function in autobody workers. Three recommendations were made to shop owners: functional paint booths should be maintained, respiratory protection programs should be developed, and isocyanate-free paints should be used. (*Am J Public Health.* 1991; 81:768–771)

Introduction

Approximately 700 autobody repair shops employ an estimated 3,500 individuals in Minnesota (Minnesota Department of Labor Relations, Personal Communication). Autobody repair involves hammering dents, removing damaged parts, welding, grinding, abrasive blasting, filling with styrene putty, sanding, and spray painting.[1,2] Workers may be exposed to hazards including isocyanates, metals in paint, solvents, dusts, and noise.[2,3] Despite possible adverse health effects,[4–7] there has been little epidemiologic investigation of the autobody repair industry.[1,8–10] This study examines pulmonary function in autobody repair workers.

Methods

Sampling Protocol

Autobody repair shops listed in the Twin Cities Yellow Pages were randomly selected for study. Shops were included in the study if: 1) they had 20 or fewer employees; 2) at least half of establishment income was from autobody repair; and 3) they were located within the Twin Cities metropolitan area. Shop owners were asked questions regarding the inclusion criteria. The owners of eligible shops were asked to participate.

A questionnaire was given to each shop manager regarding shop age, size, number of cars repaired, ventilation, and repair materials. Sampling for toluene diisocyanate (TDI), total particulates, and solvents (acetone, benzene, methyl ethyl ketone, toluene, xylene, trichloroethylene, and mineral spirits) was done in all

TABLE 1—Characteristics of 39 Autobody Repair Shops

	Mean	Standard Deviation	Range
Number of Workers	3.9	2.6	1–12
Years in Business	18.8	16.0	<1–70
Age of Building	26.4	21.9	<1–90
Repaired each Month	55.4	45.2	9–200

shops. Total isocyanates [TDI and methylene isocyanate (MDI)] were evaluated in 16 shops, lead levels in nine shops, and silica levels in seven shops. Sampling was done in a central work area for three to six hours. Pumps were calibrated before and after each sampling period. Analyses were done according to the National Institute for Occupational Safety and Health (NIOSH) Manual of Analytic Methods.[11]

A self-administered respiratory and work history questionnaire was given to each worker and reviewed with them for completeness. Using American Thoracic Society[14] criteria, pulmonary function was evaluated at the start and end of the work day with a Collins water-sealed spirometer. Measurements consisted of the forced expiratory volume at one second (FEV_1), forced vital capacity (FVC), and the FEV_1/FVC ratio. Spirometric values were adjusted for ambient temperature, barometric pressure, age, sex, and height.

Data Analysis

The shops and workers were characterized using descriptive statistics. Mantel-Haenszel odds ratios, stratified by smoking status (current, past, never) were computed for categorical variables and combined into a single summary odds ratio. Bartholomew's test for trend was used to evaluate the effect of work practices on the proportion of workers with cough or wheeze. Each of the independent variables (e.g. respirator use while sanding) was ordered as: never, sometimes, always.[15]

Percent of predicted FEV_1, FVC, and FEV_1/FVC were calculated for White males using the equations of Crapo, *et al.*[16] An "abnormal" pulmonary function test was one below the fifth percentile for age, height, and sex. The fifth percentile is a value that is approximately 80 percent of predicted for the FEV_1 and FVC, and approximately 90 percent of predicted for the FEV_1/FEC.[17] A one sample binomial test was used to evaluate the prevalence of abnormal pulmonary function tests. Morning and afternoon pulmonary function were compared using paired t-tests. Predictors of pulmonary function were evaluated using stepwise linear regression.[18]

Results

Shop Characteristics

Of the 128 shops contacted, seven (5 percent) were out of business, and 52 (41 percent) were not eligible. Of the 69 remaining shops, 59 were asked to participate of which 39 (66 percent) agreed. Ten shops were not asked to participate because *a priori* study enrollment goals had been met.

Table 1 shows the characteristics of the 39 shops studied. Two shops were one-person operations, and all but one were independently owned and operated. Even though most shops (72 percent) did sandblasting, this was rarely done for more than one hour per week. Ten shops had paint booths in a poor or nonworking condition.

Ambient levels for silica were below the detection limit for the seven shops tested. All solvent levels were below the current American Conference of Governmental Industrial Hygienists (ACGIH) guidelines. Total particulates ranged from 0.4 mg/m^3 to 14 mg/m^3. Particulate levels exceeded 5 mg/m^3 in four shops, and 10 mg/m^3 in one; the current ACGIH guideline for nuisance dusts.[19] Proton-induced x-ray analysis of ambient dusts revealed the presence of small quantities of 20 metals. No ambient lead was detected in the nine shops that were evaluated.

Isocyanate samples were collected from 32 shops. Two samples were lost due to laboratory error. Eight-hour, time-weighted average total isocyanate levels ranged from not detected to 0.06 ppm (mean = 0.005 ± 0.008). The current ACGIH recommended level for TDI and MDI is 0.005 ppm.[20] The highest and lowest isocyanate levels were from the same shop on different days. In three shops, total isocyanate levels were slightly above current ACGIH guidelines. Two to twelve times the current guideline was exceeded in another four shops.

Of 164 workers, 162 (99 percent) completed questionnaires and 159 (97 percent) performed acceptable morning and 149 (91 percent) acceptable afternoon pulmonary function tests. The mean age was 31.6 years (±11.3), 157 (97 percent) were White and 160 (99 percent) males. The mean years worked in the autobody industry was 11.4 (±9.7). Cigarette smoking was common: 67 (41 percent) current, 30 (18 percent) former, 63 (39 percent) never smokers, and two (1 percent) unknown.

Of the 122 workers who spray painted at least one hour per week, 4 percent never used a respirator while painting, 33 percent sometimes did, and 63 percent always used one. For the 96 workers who did sandblasting these percentages of respirator use were 25 percent, 33 percent, and 42 percent, respectively.

Table 2 shows the number of individuals whose pulmonary function was below the fifth percentile and the mean values of the pre-work percent predicted FEV_1, FVC, and FEV_1/FVC stratified by smoking status. Among 60 workers who had never smoked, five (8 percent) had baseline FEV_1 or FVC measurements below the fifth percentile. Fourteen (23 percent) had an FEV_1/FVC below the fifth percentile ($p < 0.001$). No significant change in pulmonary function was seen between the morning and afternoon shifts. In addition, no relationship was seen between shop isocyanate levels and pulmonary function.

By regression analysis, a nonfunctioning paint booth ($\hat{B} = -8.35$), smoking ($\hat{B} = -3.84$), years worked in the autobody industry ($\hat{B} = -0.20$), hours per week sanding ($\hat{B} = 0.21$), doing paperwork ($\hat{B} = 0.20$), and assembly ($\hat{B} = 0.18$) significantly predicted the percent predicted FEV_1/FVC ($R^2 = 0.19$). Decrements in both the percent predicted FEV_1 ($R^2 = 0.20$) and FVC ($R^2 = 0.11$) were significantly associated with years worked in the autobody industry and a nonfunctioning paint booth.

Summary odds ratios showed a positive, non-significant association between the presence of cough and wheezing* and 1) failure to have a functioning paint booth, 2) failure to use a respirator, and 3) spray painting and/or sandblasting. Using

---

*Cough was defined as coughing four to six times per day at least four days per week. Wheezing was defined as wheezing on most days or nights.

TABLE 2—Percent Predicted Morning Pulmonary Function and Number of Workers Whose Pulmonary Function Was Less Than the Fifth Percentile by Smoking Status*

Smoking Category (N)	Mean	Standard Deviation	Number with Abnormal Pulmonary Function (%)**
Never Smoker (N = 60)			
FEV_1	93.6	11.4	5 (8)
FVC	96.8	11.4	5 (8)
FEV_1/FVC	96.6	7.0	14 (23)
Former Smoker (N = 30)			
FEV_1	91.6	13.8	6 (20)
FVC	95.6	13.1	3 (10)
FEV_1/FVC	95.8	7.4	8 (27)
Current Smoker (N = 62)			
FEV_1	90.0	15.3	11 (18)
FVC	96.3	13.6	4 (6)
FEV_1/FVC	93.1	10.0	18 (29)

*A total of 159 workers completed at least one acceptable spirometric examination. Of these, five non-White workers and two workers whose smoking status was unknown were excluded from the analysis.

**Abnormal is defined as corresponding to less than the fifth percentile. For the FEV_1 and FVC this is approximately 80 percent of predicted and for the FEV_1/FVC ratio, approximately 90 percent of predicted.

a chi square test for trend, for nonsmokers, the presence of wheezing significantly ($p < 0.05$) increased across the categories of respirator use (always, sometimes, never) while spray painting and for coughing and wheezing while sandblasting. No significant trends were seen for respiratory symptoms and respirator use while sanding.

Discussion

Two-thirds of all shops contacted agreed to participate. Although no information was available on shops that refused to participate, it is unlikely that they were cleaner than the ones tested. Shops were generally dusty and strong solvent odors were common. Improper respiratory protection was often used, when used at all. These findings are similar to those of Tuskes and Key[1] and Rose, *et al.*[8]

Isocyanate levels were consistent with the mild, but significant, decline in pulmonary function and the presence of respiratory symptoms seen.[20,28] Years working in the autobody industry, and working in a shop with a nonfunctioning paint booth, along with smoking, were associated with a decrement in the FEV_1/FVC indicative of obstructive disease.[30,31] Time spent doing tasks not involving painting or priming (i.e. sanding, doing paperwork, and assembly) were positively associated with the FEV_1/FVC. No relationship was found between pulmonary function and ambient isocyanate levels. This was not surprising given the day-to-day variability in the type and quantity of work done in each shop. The failure to find acute pulmonary changes may be due to the migration of sensitized workers who may have had to find other employment or the fact that it was unusual to visit a shop on a Monday. We did not monitor over the course of the week for delayed asthmatic reactions.[26]

The environment in autobody repair shops may be improved in several ways. Shops should maintain functional paint booths for spray painting, and the spray painting of vehicles in open shop areas should be avoided. Shops should have complete respiratory protection programs and use less hazardous, isocyanate-free paints. ☐

Measuring Physical Activity With a Single Question

Kenneth B. Schechtman, PhD, Benico Barzilai, MD, Kathryn Rost, PhD, and Edwin B. Fisher, Jr, PhD

ABSTRACT

Using 1,004 subjects enrolled in a worksite health promotion program, this report evaluated the validity of a single question about participation in regular exercise. Measured at baseline, this one question had a significant age-adjusted association with body mass index ($p < 0.0001$ in women and $p = 0.001$ in men), HDL cholesterol ($p < 0.0001$ in women), and oxygen capacity ($p = 0.0007$ in women and $p = 0.002$ in men). Thus, one self-reported question can provide useful information about who is and who is not participating in regular exercise. The potential validity of a single exercise question is particularly relevant in complex epidemiologic studies where lengthy questionnaires highlight the importance of brief instruments. (*Am J Public Health.* 1991;81:771–773)

Introduction

Through its association with low levels of HDL (high-density lipoprotein) cholesterol, obesity, and other physiologic parameters, physical inactivity has been linked to increased morbidity and mortality from a variety of diseases. These include cardiovascular diseases,[1] diabetes mellitus,[2] osteoporosis,[3] and even breast cancer[4] and colon cancer[5]. In light of these etiologic associations, the measurement of physical activity has become a standard component of epidemiologic research, with at least 30 different measurement techniques having been described.[6] Unfortunately, many of these are complex instruments that are associated with excessive costs and time commitments that make them impractical in large-scale epidemiologic studies.[6,7] Thus, there is great value in establishing the validity of brief, easily obtained measures of physical activity.

It is the purpose of the present report to discuss the utility of a single exercise question that was generated by the St. Louis Working Hearts Program. That question was "Do you currently participate in any regular activity or program (either on your own or in a formal class) designed to improve or maintain your physical fitness?" We will investigate the validity of this question by evaluating its association with three parameters that are known to be associated with physical activity: body mass index (BMI), HDL cholesterol, and oxygen capacity.

Methods

The data discussed herein were generated by Working Hearts, a four-year collaboration between Washington University in St. Louis and a large midwestern communications corporation. All employees at 17 divisions of the corporation were eligible to participate in a multifaceted two-year cardiovascular risk reduction intervention. The intervention included individualized counseling, worksite promotional activities, and 25 awareness seminars and workshops that focused on weight loss, cholesterol reduction, hypertension, exercise, stress reduction, diet, and smoking cessation. Of particular relevance is the fact that the exercise component of the intervention included discussions and workshops, but no regular exercise program. Data on three of the four variables pertinent to this report—exercise behavior, BMI, and HDL cholesterol levels—were sought from all study participants. BMI was de-

TABLE 1—Oxygen Capacity and Baseline Body Mass Index and HDL Cholesterol by Exercise Status at Baseline (Data are expressed as mean ± standard deviation)

	Exercise Status		
Panel A: Women	No (N = 517)	Yes (N = 154)	Age-Adjusted p-value
Oxygen Capacity[1]	28.8 ± 7.5	32.3 ± 7.2	0.0007
Body Mass Index	26.7 ± 6.1	24.2 ± 4.4	0.0001
HDL Cholesterol	57.0 ± 13.4	61.5 ± 14.3	0.0001
Panel B: Men	No (N = 201)	Yes (N = 114)	Age-Adjusted p-value
Oxygen Capacity[1]	33.8 ± 7.5	40.3 ± 8.3	0.002
Body Mass Index	27.6 ± 4.0	26.1 ± 3.2	0.001
HDL Cholesterol	47.2 ± 12.2	48.2 ± 10.2	0.455

[1] Oxygen capacity data were available on 81 women and 33 men involved in vigorous exercise and 155 women and 35 men not involved in vigorous exercise. The unit of measurements is ml/kg/min.

fined as weight (in kg) divided by height (in meters) squared. Oxygen capacity, in ml/kg/min, was measured on a self-selected subset of 304 subjects using a sub-maximal bicycle test. Results, expressed as mean ± standard deviation, are analyzed separately for males and females. Analysis of covariance determined whether there were significant age-adjusted differences in the three relevant parameters between exercising and non-exercising subjects. To analyze changes over time, the 591 participants who provided both baseline and final exercise data were divided into four groups as follows: Group NN responded "no" at both times (N = 281, 47.5 percent); Group YY responded "yes" at both times (N = 130, 22.0 percent); Group NY reported initiating exercise (N = 118, 20.0 percent); and Group YN reported cessation of regular exercise (N = 62, 10.5 percent).

Results

The Working Hearts data set contained 1,004 subjects whose age was 36.6 ± 9.5 years; 73.1 percent were female. Among the 986 subjects who provided baseline exercise information, 32 percent (N = 316) reported participation in regular exercise. Subjects who provided oxygen capacity data (N = 304) were younger (p = 0.001 in women, p = 0.012 in men), had a lower baseline BMI (p = 0.036 in women, p = 0.049 in men), and were more likely to exercise at baseline among women (p = 0.008) but not among men (p = 0.265), than those not providing oxygen capacity data. However, after age adjustment, logistic regression found that BMI had no independent association with the availability of bicycle test data in either sex, but that baseline exercise was still significant in women (p = 0.030). The availability of bicycle test data was not associated with baseline HDL cholesterol in either sex.

Table 1 provides the key data summarizing the validity of the simplified exercise measure we have utilized. It indicates that at baseline, and after age adjustment, subjects who said they were exercisers had a lower BMI (p < 0.0001 in women and p = 0.001 in men), greater oxygen capacity (p = 0.0007 in women and p = 0.002 in men), and had a higher HDL cholesterol (p < 0.0001 in women) than those who did not report participation in regular exercise.

Using the four groups defined in the Methods section, Table 2 contains the mean change from baseline to final measurement in both BMI and HDL cholesterol. Oxygen capacity was not evaluated in this context because it was measured at only one time point. Following age adjustment, mean HDL cholesterol was not the same in all four groups of men (p = 0.007). Statistical contrasts show that this reflected an *increase* in HDL in group YY (2.2 ± 11.5, N = 58) that was significantly

TABLE 2—Changes in Body Mass Index and HDL Cholesterol by Exercise Status[a] (Data are expressed as mean ± standard deviation)

	Group NN	Group NY	Group YN	Group YY	
Panel A: Women	(N = 209)	(N = 92)	(N = 43)	(N = 69)	Age-Adjusted p-value[b]
Change in body Mass Index	0.59 ± 1.9	0.05 ± 2.2	0.69 ± 2.2	0.23 ± 1.7	0.100
	Contrasts:[c] Group NN vs Group NY: p = 0.028				
Change in HDL Cholesterol	−1.3 ± 10.7	−2.2 ± 6.7	−3.3 ± 11.5	−2.8 ± 7.9	0.655
	Group NN	Group NY	Group YN	Group YY	
Panel B: Men	(N = 72)	(N = 26)	(N = 19)	(N = 61)	Age-Adjusted p-value[b]
Change in body Mass Index	0.33 ± 1.3	−0.47 ± 1.5	−0.02 ± 0.87	−0.08 ± 2.5	0.218
Change in HDL Cholesterol	−3.0 ± 6.4	−1.7 ± 6.4	−1.0 ± 4.9	2.2 ± 11.5	0.007
	Contrasts:[c] Group NN vs Group YY: p = 0.0006				

[a] Exercise groups are: Group NN = No exercise at baseline or final screening; Group NY = Not exercising at baseline, exercising at final screening; Group YN = Exercising at baseline but not at final screening; Group YY = Exercising at both time points.

[b] Based on analysis of variance testing equality in all four groups and adjusting for age.

[c] Not adjusted for multiple comparisons.

different from the *decrease* in HDL cholesterol in group NN (−3.0 ± 6.4, $p = 0.0006$, $N = 70$). Although the overall age-adjusted ANOVA showed no difference in BMI among the four groups of women ($p = 0.100$), it is worth noting that the statistical contrast comparing the increase in BMI in group NN (0.59 ± 1.9) with the small change in group NY (0.05 ± 2.2) was significant ($p = 0.028$).

Discussion

These results indicate that among Working Hearts subjects, a single self-reported measure of participation in regular exercise at baseline was significantly associated, after age adjustment, with body mass index and oxygen capacity in both sexes and with HDL cholesterol in women. Thus, our data support several other studies[8-10] which have suggested that simple self-reported instruments can yield valid information about participation in regular exercise. Based on only two exercise questions, for example, the Lipid Research Clinics Study[8] found that subjects who reported regular vigorous exercise had higher HDL cholesterol, lower resting heart rates, and longer exercise test durations than those not reporting regular exercise. Siconolfi et al[9] found that a single question concerning the self-reported frequency of exercise that induced sweating was associated with maximal oxygen uptake.

If a prime focus of a study is to gain detailed and precise information about levels of physical activity, extensive exercise questionnaires are required. Our results suggest, despite some positive associations in Table 2, that simplified exercise measures may also be inadequate when changes over time are of primary interest. However, as with the reports noted above,[8-10] our data argue strongly that one or two self-administered questions can provide a valid measure of who is and who is not currently involved in regular exercise. Thus, when extensive questionnaires place great demands on participants in a multifaceted epidemiologic study, and when detailed information about exercise behavior is not essential, a few simple exercise questions may be an appropriate alternative to the complex instruments that are frequently utilized. ☐

Public Health and the Law

OSHA's Four Inconsistent Carcinogen Policies

Background

No issue has proven more contentious in occupational health policy than the control of chemical carcinogens. The Occupational Safety and Health Administration (OSHA) has focused much of its efforts on cancer risks, both through substance-specific regulations and through broader efforts to establish generic policies and work practices. The 1980 Generic Carcinogen Policy was conceptualized as the centerpiece of OSHA's shift from substance-specific to generic regulations covering hundreds if not thousands of substances. Despite adverse judicial rulings and a generally anti-regulatory political climate, OSHA continued to pursue a generic approach to occupational health hazards during the 1980s, particularly through its 1983 Hazard Communication Standard and 1989 Air Contaminants Standard. The legal and political wrangling have left deep scars on OSHA's strategy, however. While consistency and comprehensiveness were once the principles underlying OSHA's efforts to control carcinogens, the current collection of policies and regulations is remarkable for the inconsistent and incomplete way in which suspect chemicals are treated.

In this paper, we analyze OSHA's four carcinogen strategies, as embodied in the Generic Carcinogen Policy, the substance-specific carcinogen regulations, the Hazard Communication Standard, and the Air Contaminants Standard. Two issues are of particular interest.

- Given the inherent methodological limitations to epidemiological data on occupational and environmental cancer, a major scientific and policy debate has developed over the appropriate use in human risk assessment of laboratory evidence on chemical carcinogenesis in animals. The four OSHA policies exhibit quite different positions on this debate.
- The choice between direct regulation and indirect labor market pressure, and the stringency of those exposure limits that are imposed, reflect different attitudes toward the appropriate balance of economic costs and health benefits for occupational health regulations. OSHA's four policies reflect dramatically different balancing efforts.

We begin with the Generic Carcinogen Policy, which remains OSHA's formal policy on the issue but which has been blocked by administrative stays and never incorporated into risk management programs. The substance-specific cancer standards are then analyzed in terms of their comprehensive treatment of a few public health hazards and neglect of many others. While partially an attempt to preempt stronger state and local regulations, the Hazard Communication Standard is in many ways both comprehensive and innovative, covering a wide range of chemicals and imposing duties on employers that could potentially lead to substitution of alternative products and processes. Given its current prominence as the centerpiece of OSHA's regulatory program, the Air Contaminants Standard receives the greatest emphasis. Containing its own internal inconsistencies, the Air Contaminants Standard embodies the best and the worst of OSHA's new regulatory philosophy and its strategy for controlling chemical carcinogens in the workplace.

The Generic Carcinogen Policy

OSHA's Generic Carcinogen Policy[1] was a response to two complementary concerns that emerged over the course of the 1970s and came to dominate the agency's agenda. OSHA had devoted a substantial portion of its resources to the regulation of individual carcinogens but had achieved only meagre results. The agency leadership faced growing demand for an accelerated regulatory timetable from Congress, organized labor, and environmental groups. Of equal significance, perhaps, was the competition among several federal agencies for leadership in formulating governmental policies with respect to chemical carcinogens. Proposed in 1977 and promulgated in 1980, OSHA's Generic Carcinogen Policy embodied a highly protective approach to chemical carcinogenesis. Based on the most conservative set of assumptions concerning methods of cancer induction and the most stringent set of requirements for exposure controls, the 1980 policy represents the high water mark of governmental enthusiasm for regulating occupational and environmental carcinogens.

OSHA devoted much of its energies during the 1970s to developing standards regulating exposure to occupational carcinogens, including asbestos[2] in 1972, vinyl chloride[3] and a group of 14 chemicals[4] in 1974, coke oven emissions[5] in 1976, plus benzene,[6] dibromochloropropane (DBCP),[7] inorganic arsenic,[8] and acry-

lonitrile[9] in 1978. All of these except the DBCP and acrylonitrile standards underwent court challenges from the regulated industries, with lengthy delays and threats of reversal. A number of "science policy" issues reappeared at each challenge, including the relevance of animal data for human carcinogenesis, the importance of negative study results compared to positive results, the correlation between induction of benign and malignant tumors, and the purported existence of a threshold for carcinogenic effects. These same policy issues were being raised at EPA with respect to pesticides covered by the Federal Insecticide, Fungicide, and Rodenticide Act[10] and toxic air pollutants covered by the Clean Air Act.[11] After some discussions with EPA over the possibility of a joint carcinogen policy, OSHA decided to proceed with its own standard. The history of the OSHA policy and its relationship with initiatives at other regulatory agencies has been described in detail in several publications.[12–17]

The Generic Carcinogen Policy established a categorization system for known or suspected chemical carcinogens, with immediate regulatory action being proposed for substances falling into Category I. This category would be composed of substances that increased the incidence of benign or malignant tumors or decreased the latency period between exposure and onset in humans, in two animal species, in a single mammalian species in two or more independent experiments, or in a single experiment if supported by evidence from short-term tests. Within the universe of substances falling into Category I, the policy established a priority setting mechanism whereby the agency would select 10 substances for comprehensive standard setting at any one time, to include requirements for exposure limits, monitoring, worker training, and other factors. In 1980, OSHA issued a candidate list of 204 chemicals for review as possible candidates under the terms of the policy. The exposure limits were to be set at the lowest "feasible" level, which was interpreted by the agency as accepting any level of compliance costs short of causing massive economic dislocation and job loss in the regulated industry.

The weakening of the Generic Carcinogen Policy began almost as soon as it was promulgated. In July of 1980, the United States Supreme Court upheld the decision by the Fifth Circuit Court of Appeals to vacate the standard governing occupational exposure to benzene, on the grounds that OSHA had not proven that exposures to benzene at the level regulated by the standard posed a "significant risk" to employees.[18] This ruling implied that any standard not demonstrating significant risk, presumably through the emerging quantitative risk assessment methodologies, would be overturned. The types of evidence sufficient to qualify chemicals for OSHA's Category I did not demonstrate "significant risk" without further analysis. In January of 1981, OSHA issued a revised Generic Carcinogen Policy that mandated a two-part approach to characterization of individual carcinogens.[19] An initial qualitative assessment would be made in accordance with the original categorization system. For each particular substance falling into Category I, an assessment would be made of whether current exposure levels constituted a significant risk. Those chemicals considered to pose such a risk would be regulated down to the lowest feasible level, as before.

Of greater import for the Generic Carcinogen Policy was the presidential inauguration several days later of Ronald Reagan. OSHA's cancer policy was listed by the new Administration's Task Force on Regulatory Relief as one of the first 27 regulations to be reconsidered due to their economic costs. On March 27, 1981, the Generic Carcinogen Policy amendments proposed in January were withdrawn in order to permit OSHA to "address alternatives that had not been fully considered."[20] The policy remained in abeyance from then on. In January of 1982, OSHA officially proposed a partial stay on the publishing of the Candidate and Priority Lists of chemicals[21]; this stay was promulgated a year later.[22]

These actions were largely of symbolic importance, since the agency was not pursuing the hazard identification and regulation provisions of the Generic Carcinogen Policy in any case. In August of 1986, the agency announced its intention to propose rulemaking to revise the standard, but did not follow up with any substantive initiative.[23] In February 1987, the Fifth Circuit Court of Appeals dismissed 16 petitions filed by industry and labor groups concerning various provisions of the Generic Carcinogen Policy on the grounds that nothing had happened in six years and hence that it could be considered dormant.[24] Nevertheless the Generic Carcinogen Policy has remained as OSHA's official policy.[25] The National Institute for Occupational Safety and Health (NIOSH) continues to propose lowest feasible level regulations for substances with laboratory evidence of carcinogenicity, under the authority of the Generic Carcinogen Policy.[26,27] This implies that only a relatively simple administrative decision might be sufficient to revive the policy, a matter of concern for industry groups and the Reagan Administration as the election of 1988 approached. The industry-sponsored American Industrial Health Council and the federal Office of Management and Budget (OMB) both recommended that rulemaking be pursued by OSHA to officially excise the offensive parts of the policy.[28,29] The OMB was particularly harsh on OSHA for allowing the timetable of deregulation to slip, declaring its concern for the Reagan "legacy" and noting that "there is only so much time left." Nevertheless, no action was taken on the policy.

The Generic Carcinogen Policy represents OSHA's most aggressive initiative directed at occupational carcinogens. It embodies all the most conservative, health-protective assumptions about the biological process of carcinogenesis. Of greatest importance, it declares that regulation should proceed for those chemicals for which there exists laboratory but not yet epidemiological evidence of cancer effects. The policy weighs the costs and benefits of regulation in a manner strongly oriented toward regulation. OSHA's definition of "feasible" is a highly stringent one. While not unique in its adoption of this concept of feasibility, the Generic Carcinogen Policy stands out in its effort to expeditiously extend the principle to a sweeping array of chemicals.

Substance-Specific Regulations

OSHA continued to promulgate substance-specific standards in the 1980s, but now with even less success than during the previous decade. The battles of the 1970s had produced three legal and institutional barriers to aggressive regulation of occupational carcinogens which continue to haunt the agency to the present.

- First, the Supreme Court's "significant risk" doctrine underlying the dismissal of the original benzene standard requires the agency to perform a detailed quantitative risk assessment for each candidate carcinogen.
- Second, industry concern over the economic costs of compliance contributed to the development of an increasingly rigorous set of requirements for the agency to estimate the economic impact of each proposed regulation. This requirement for economic studies originated with President Gerald Ford,[30] was extended by

President Jimmy Carter,[31] and culminated with President Reagan's requirement for formal cost-benefit analysis.[32] While OSHA's health standards are officially exempt from these cost-benefit requirements due to a Supreme Court ruling on the cotton dust standard,[33] the agency is required to produce rigorous analyses of the expected cost of compliance with its standards.

- Third, the regulatory strategy of the 1970s raised OSHA to a position of high visibility and vulnerability with respect to the Office of Management and Budget, which has interpreted its role as one of reining in a regulatory process gone amok.[34]

Given these impediments and the general anti-regulatory mood of the Reagan Administration, it is perhaps remarkable that OSHA completed any cancer regulations at all. Its record of achievement during the 1980s was quite modest, consisting of leftover business from the previous decade in the form of the revised benzene[35] and asbestos[36] standards plus the promulgation of two new regulations governing ethylene oxide[37] and formaldehyde.[38]

Two features characterize OSHA's new substance-specific regulations. First, they all cover substances for which there exists epidemiological evidence of carcinogenicity in worker populations. While this might charitably be interpreted as beginning at the top of a priority list similar to those produced by the Generic Carcinogen Policy, it actually constitutes a rejection of the guiding principle of the Generic Carcinogen Policy, namely that regulation should proceed based on animal evidence without waiting for epidemiological studies. The Generic Carcinogen Policy was consciously designed to make the transition from epidemiology to animal laboratory evidence as the basis for OSHA regulations; the similarity between the substance-specific regulations of the 1980s and their counterparts in the 1970s eloquently testifies to the failure of this transition. The substance-specific regulations also symbolize the abandonment of OSHA's efforts to provide leadership for the federal regulatory agencies. This role has now reverted to EPA, which has a carcinogen policy that relies heavily on animal evidence.[39] The second salient feature of the substance-specific regulations is their relative stringency. The permissible exposure limit was reduced by 90 percent in the cases of asbestos and benzene, by 98 percent in the case of ethylene oxide, and by 66 percent in the case of formaldehyde.

The Hazard Communication Standard

The most important standard promulgated by OSHA during the 1980s was the Hazard Communication Standard,[40] which requires labeling of hazardous substances and the development of training programs for workers. While less stringent than the Hazard Identification Standard which was proposed by the Carter Administration[41] and withdrawn in the first months of the Reagan Administration,[42] the Hazard Communication Standard is nevertheless sweeping in scope and potentially significant in impact. Although not focused on carcinogens, the Hazard Communication Standard does impose important new obligations on produces and users of these substances.

The Hazard Communication Standard is officially a "performance standard" which delegates to industry management the right and responsibility to decide which substances are to be included in the labeling and training programs. Nevertheless, the Standard does provide a floor of substances that must be included. This includes chemicals listed as carcinogens by the International Agency for Research on Cancer (IARC) of the World Health Organization[43] plus chemicals included in the National Toxicology Program's (NTP) *Annual Report on Carcinogens*.[44] In addition, chemicals must be designated as potential carcinogens and included in worker training programs if they have produced evidence of carcinogenicity in any well-conducted laboratory studies. According to one estimate, these provisions mandate inclusion of 416 substances based on the IARC and NTP documents plus an additional 2,260 substances with laboratory evidence of carcinogenicity but which are not classified by IARC or NTP.[45] This broad scope of substances immediately evokes the Generic Carcinogen Policy, since it places laboratory data front and center in establishing which substances will be classified as potential occupational carcinogens. Less than 1 percent of these substances have strong epidemiological evidence of carcinogenicity in humans.

While similar to the Generic Carcinogen Policy in terms of scope, the Hazard Communication Standard differs markedly in terms of regulatory requirements. It imposes no permissible exposure limits, much less ones that are the lowest feasible short of ruining the industry. Under the terms of the Standard, chemical manufacturers must prepare summaries of available toxicological and epidemiological information, in the form of a Material Safety Data Sheet (MSDS), and provide these to all purchasers of their products. Manufacturers are also responsible for the labeling of containers of hazardous substances; these labels contain brief warnings and refer to the relevant MSDS. All users of covered substances, not just chemical manufacturers, must develop written hazard communication programs that detail how they will comply with the Standard. These users must also organize worker training sessions which cover the information on the labels and MSDS plus proper handling procedures.

The Hazard Communication Standard provides no direct protections but relies upon worker responses to the new information for its ultimate efficacy. In principle, these responses could occur via turnover[46–48] or collective bargaining.[49–51] While modest in the startup costs it imposes on employers, the Hazard Communication standard has the potential to alter management treatment of suspect carcinogens over the long term. In the short term, however, the Standard's effectiveness will be limited by the poor quality of the MSDS and employer training programs currently in place.[52]

The Air Contaminants Standard

A dramatic departure from substance-specific rulemaking, OSHA's 1989 Air Contaminants Standard[53] imposed permissible exposure limits (PELs) on 164 substances not previously regulated and lowered the PELs for an additional 212 substances that had been regulated under the start-up provisions of the original 1970 Occupational Safety and Health Act. Hailed as the centerpiece of a new approach to standard setting, the Air Contaminants Standard has also been severely critized for the procedure used in selecting chemicals and for its choice of exposure limits.

The Air Contaminants Standard is explicitly based upon the Threshold Limit Values (TLVs) of the American Conference of Governmental Industrial Hygienists (ACGIH), a private non-governmental organization, whereas the 1970 OSH Act designates NIOSH as the primary source for recommended standards. The TLVs and the process by which they are

TABLE 1—Number of Substances Classified as Confirmed or Potential Human Carcinogens by Five Scientific Organizations, and Number of Classified as Carcinogens by OSHA's Four Carcinogen Policies

Hazard Communication Standard	none	yes	no
Air Contaminants Standard	weak	no	no

established have come under increased scrutiny, partly as a result of OSHA's reliance upon them. Analysis of the minutes of the TLV committee and other documents has uncovered a major but unacknowledged role played by the producers of the chemicals.[54] An analysis of the epidemiological studies referenced as part of the documentation for the TLVs found that the TLVs were generally established at levels commonly reported as prevalent in industry rather than at levels below which no significant adverse health effects were reported.[55] The TLV-based PELs for 98 substances in the Air Contaminants Standard were considered insufficiently protective by NIOSH.[56] Both industry and labor representatives asserted that the PELs mandated by the Air Contaminants Standard may create some problems of compliance for small firms but none for major producers.[57]

The treatment of occupational carcinogens under the Air Contaminants Standard is inconsistent and incomplete. While 78 of the substances covered by the Standard are considered confirmed or potential human carcinogens by NIOSH, ACGIH, and/or NTP, only 11 are regulated under the standard based on cancer risks. The others are regulated based on noncarcinogenic effects. Excluded altogether from the Air Contaminants Standard are 68 substances considered to be confirmed or potential human carcinogens by NIOSH, ACGIH, and/or NTP.[58]

The Air Contaminants Standard makes no consistent distinction between epidemiological and laboratory evidence in regulating substances as carcinogens. Of the 11 substances regulated as carcinogens, six had epidemiological evidence of cancer effects in workers while five had only laboratory evidence of cancer in animals. Of the 67 substances regulated based on noncarcinogenic effects alone, five were considered confirmed human carcinogens by NIOSH, ACGIH, and/or NTP based on epidemiological evidence. Of the 68 substances considered as confirmed or potential carcinogens by the three scientific bodies but excluded altogether from the standard, 11 had epidemiological evidence of cancer in humans.

The Air Contaminants Standard is also inconsistent in the stringency of the exposure limits placed on particular substances. Of the 11 substances designated as carcinogens, seven have PELs set equal to the TLV, three have PELs set lower than the TLV, and one has a PEL set higher than the TLV. OSHA computed the residual risk of cancer (maximum likelihood estimate) for workers exposed to seven of these 11 substances at the new PELs. These residual cancer risks ranged from 0.3 cases per 1,000 workers to 40 per 1,000, with a median of 3.7 and a mean of 10.1. By way of comparison, the maximum likelihood estimates of the residual risk under the substance-specific standards promulgated during the 1980s ranged from 0.0006 per 1,000 for formaldehyde[59] to 1.7 per 1,000 for ethylene oxide,[60] 6.7 per 1,000 for asbestos,[61] and up to 9.5 per 1,000 for benzene.[62]

Conclusion

OSHA's official cancer policy, the 1980 Generic Carcinogen Policy, is comprehensive in the universe of substances covered and stringent in the exposure limitations proposed, but languishes in ignominious neglect. The substance-specific regulations present a politically risk-averse contrast. Eschewing chemicals lacking epidemiological evidence of cancer in humans, they devote enormous resources to documenting significant risk and economic feasibility and impose permissible exposure limits on a very few substances. The 1983 Hazard Communication Standard rivals the Generic Carcinogen Policy in the scope of substances covered but establishes a quite different and less direct form of incentives for management to reduce workplace exposures. The 1989 Air Contaminants Standard rivals the Generic Carcinogen Policy in imposing permissible exposure limits for hundreds of toxic chemicals, but abandons internal consistency with respect to the stringency of the particular limits imposed and external consistency with the recommendations from scientific bodies.

The inconsistencies between OSHA's four carcinogen policies are highlighted on Tables 1 and 2. Table 1 presents the number of substances commonly found in the US workplace environment that are designated as confirmed or potential human carcinogens by five scientific bodies, plus the number of substances on each of these five lists that is covered by each of OSHA's four carcinogen policies.[53] The breadth of the Generic Carcinogen Policy and the Hazard Communication Standard is illustrated by their coverage of all substances listed by the five scientific bodies. In start contrast, OSHA's substance-specific regulations and the Air Contaminants Standard cover only a very small fraction of the listed carcinogens. Most remarkable, perhaps, is the contrast between cancer designations in the Air Contaminants Standard and the designations by NIOSH, the organization to which OSHA officially responds. NIOSH considers 76 of the substances covered by the Air Contaminants Standard to be potential human carcinogens, but OSHA only set 11 permissible exposure limits based on avoidance of cancer risk. The Standard excludes altogether 26 substances considered occupational carcinogens by NIOSH.

Table 2 describes that risk management strategy embodied in each of OSHA's four carcinogen policies. Two of the policies impose stringent permissible exposure limits, one imposes weak limits, and one imposes none. The encouragement of worker self-help initiatives through container labeling and employee training is comprehensive in three policies but absent from the Air Contaminants Standard. Only the Generic Carcinogen Policy and the substance-specific regulations contain provisions for exposure monitoring and medical surveillance.

Progress in society's efforts to reduce the incidence of work-related cancer will only come as part of a general reform of occupational health policy at OSHA. On the political front, the shortest odds are for continued stalemate and perpetuation of the status quo. Among outside observers of OSHA's policies, however, a consensus may be growing as to a way to save generic rulemaking.[13,64] This would involve a major compromise to give up the illusion of imposing exposure limits at the lowest feasible level, in exchange for the ability to rely upon animal evidence of carcinogenicity and hence accelerate the pace of standard-setting. Briefly, OSHA could focus on a wide range of substances for which the available evidence might not survive a "significant risk" judical review but which could pass a less stringent "material impairment of health" review. For these substances, OSHA could impose moderate "best available technology" standards modeled upon EPA experiences with the Clean Water Act.[65] More stringent (lowest feasible) standards would be reserved for the much smaller class of substances that could withstand a "significant risk" review.

This proposal is certain to elicit criticism both from those dissatisfied with the outcome of technology-based standards for environmental regulation and from those attached to the symbolic value of the "lowest feasible" regulatory approach. Technology-based standards provide no guarantee that the residual risks are acceptably low and may create disincentives for industry to develop new control methods that might then be mandated as the "best available."[66] Nevertheless, the technology-based approach retains its pragmatic appeal and has been incorporated for the control of hazardous air pollutants in the revised Clean Air Act.[67] As for critics insistent on OSHA's lowest feasible level strategy, the fate of OSHA's Generic Carcinogen Policy should serve as a note of caution. The real world of power and politics seems to offer stringent limits and narrow scope, as in the substance-specific standards, or broad scope and weak limits, as in the Air Contaminants Standard. What is needed is a mutually consistent and supportive set of standards that deal with each different aspect of the overall risk management strategy. When combined with the Hazard Communication Standard and the proposed generic exposure monitoring and medical surveillance standards,[68,69] an appropriately revised exposure limit policy could provide the foundations for an effective generic approach to controlling occupational carcinogens. ☐

Health Care Received by American Children: NCHS Report

The vast majority (83 percent) of American children are covered by health insurance, have a regular source of health care (88 percent), and visited a doctor in the past year for routine health care (64 percent) according to a recent report issued by the National Center for Health Statistics. The report cites new evidence, however, that America's minority and poor children receive less care, including preventive services.

The report, *Health Insurance and Medical Care: Health of Our Nation's Children, United States, 1988*, is derived from data from the 1988 National Health Interview Survey on Child Health, conducted by NCHS. Questions on health insurance and sources of medical care were asked for for all 17,110 children in a nationally representative sample of children 17 years of age and under.

The survey shows that Black newborns and infants were 2 to 3 times more likely to have lacked a routine visit for a check-up or any immunization during the first year of life than were White newborns and infants. Hispanic children were twice as likely to have no health insurance coverage, either public or private, as non-Hispanics.

Most children with a regular source of health care had private care; however, 16 percent of those children (8.7 million) received health care from hospital clinics, emergency rooms, walk-in or emergency centers or other clinics. Clinics were the source of care for 47 percent of Black infants, compared to 16 percent of White infants. For Hispanic infants, almost half received health care in clinics.

The report, *Health Insurance and Medical Care: Health of Our Nation's Children, United States, 1988* is available from the National Center for Health Statistics, Centers for Disease Control, US Public Health Service, 6525 Belcrest Road, Hyattsville, MD 20782; (301) 436-8500.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health*, 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Copying done for other than personal or internal reference use—such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale—without the expressed permission of the American Public Health Association is prohibited. Requests for special permission or bulk orders should be addressed to APHA headquarters.

The American Journal of Public Health is indexed in whole or in part in these data bases: Bibliographic Index of Health Education Periodicals, Biological Abstracts, Biology Digest, BRS Bibliographic Retrieval Service Inc, Chemical Abstracts, Cumulative Index to Nursing & Allied Health Literature, Environmental Information Center Inc., Environmental Periodicals Bibliography, Excerpta Medica, Grateful Med, Hospital Literature Index, Hospital Management Review, Human Resources Abstracts, Index Medicus (Abridged), MEDLARS, MEDSOC, Nuclear Science Abstracts, Physical Education Index, Public Affairs Information Service, Public Health Reviews, Safety Science Abstracts, Sage Family Studies Abstracts, Science Citation Index, and Social Work Research and Abstracts.

Commentary

How Blind Is Blind Review?

Alfred Yankauer, MD, MPH

ABSTRACT

Background: No representative surveys of scientific opinion about blind review have been published, and there is very little information on the success of the blinding process. The *American Journal of Public Health* has practiced blind review since 1977.

Methods: In 1989 to 1990 312 of its reviewers were asked to identify author and institution in the manuscript they reviewed, to provide clues to such identification, to express their opinion concerning blind review, and to offer reasons for their opinion.

Results: Reviewers claimed to be able to identify author and/or institution in 47% of the 614 chances offered; identification was incorrect 16% of the time, overall identification correct 39% of the time. Self-referencing was the clue to identification in 62%, personal knowledge in 38% of the cases. If only personal knowledge cases are considered, blinding was successful 83% of the time. Blinding was favored by 75% of the reviewers with most asserting it eliminated bias. Reasons given for opposing blind review included the following: blinding not possible, identification will not influence judgment, and its obverse, identification assists judgment.

Conclusions: For the *American Journal of Public Health* blinding is usually, but not always, successful; and the majority of its reviewers favor current policy. Until more definitive data are in, reviewer preference, which differs from journal to journal, seems the most legitimate guide to journal policy on blind review. (*Am J Public Health*. 1991;81:843–845)

Introduction

Whether or not to blind reviewers to the identity of the authors whose papers they are asked to review has been hotly debated for at least 20 years. In spite of firmly held opinions pro and con, no representative surveys of scientific opinion have been reported, and there is very little information on the prevalence of blinding as a practice or on the success of the blinding process.

Four surveys of the frequency of blinding have been published,[1–4] but none is based on a random sampling of journals from different scientific disciplines, and their size and response rates often leave something to be desired. Their results suggest that the majority of scientific journals do not practice blind review and that blinding may be more common in the social sciences than in the physical and medical sciences.

Small, narrowly focused studies of reviewer opinion about the desirability of blind review report varying proportions in favor of review: 39% with 11% having no opinion (personal communication, Lew Gidez, FASEB), 41% *(Diabetes Care)*,[5] 49% (37% no opinion, *J Neuropathol-Exp Neurol*),[6] and 89% *(Schol Publ)*.[7]

Personal opinions of the success of blinding not based on actual study also vary: 33%,[8] 50% to 60%,[9] and 90%.[10] The reported success of blinding in *J Neuropathol Exp Neurol* was 66% when 55% of all eligible manuscripts were eliminated because of self-referencing,[6] and 73% *(Arch Intern Med)*[11] when self-referencing was partially eliminated.

Reviewer opinions about signing their reviews will be influenced by journal policy. Some journals have encouraged reviewers to sign their reviews arguing that the review process should be completely open. Journals which encourage the practice report a signing rate of only 43% *(Arch Intern Med)*[11] and 58% *(J Lab Clin Med)*.[12] *Diabetes Care* reported that 80% of its reviewers opposed mandatory signing, but 53% favored optional signing.[5] Two other small reviewer surveys report 77% *(Schol Publ)*[7] and 46%[6] (47% no opinion) favoring anonymity for reviewers.

The editorial board of the *American Journal of Public Health (AJPH)* voted to adopt a policy of blind review in 1976. I was skeptical about its value but agreed to survey reviewer opinion. After the first hundred reviewer returns, it was evident that the vast majority of *AJPH* reviewers favored blind review, and the policy was implemented in 1977. In the 13 following years only two of more than 1000 reviewers have refused to review a manuscript because of the blinding policy.

Contributors to *AJPH* are instructed to submit a second face sheet which includes only the title of the paper. These instructions are usually followed. We remove acknowledgments, but make no further effort to remove identifying page headers (when present contrary to instructions) or to change the text or references. We have been aware that a substantial proportion of our manuscripts are not truly blinded because of text allusions and

TABLE 1—Proportion of Correct Identifications of Author and Institution According to "Yes" and "Maybe" Responses

	Author		Institution		Total	
Response Type	%	n	%	n	%	n
Yes	96	(67)	89	(87)	92	(154)
Maybe	70	(66)	80	(66)	75	(132)
Total	83	(133)	85	(153)	84	(286)[b]

[a]Difference in proportion: Yes-Maybe total = 17 (95% correct identifications, 25.5, 6.5).
[b]Both chances taken: 112; Author only taken: 24; Institution only taken: 38.

TABLE 2—Proportion of Correct Identifications of Author and Institutions According to Type of Chance Taken

		Correct Identification (%)	
Type of Chance Taken	N	Author	Institution
Author only	24	83	—
Institution only	38	—	82
Both author and institution	112	83	87
Total	286[a]	83	85

[a]Both chances taken doubled in total.

self-referencing; we so inform reviewers in a covering letter that accompanies the manuscript.

Because of the current interest in blinding I undertook a more extended study in late 1989 and early 1990. Its purpose was to find out how often blinding was successful, to identify the give-away clues, and to determine the opinions of our reviewers about the policy. Our communications to the reviewer were unchanged except for the addition of a questionnaire.

Methods

A short questionnaire was sent to reviewers with consecutive blinded manuscripts. It asked whether author and institution were identifiable (yes/no/maybe) and if so, to record their names and describe the clues that led to their identification. Identification was considered correct if any one of the several authors or institutions represented were listed in the response. A second set of questions asked whether they favored blind review (yes/no) and their reasons for such an opinion. Reviewers were asked to return the form to the editor with their review. They were requested to complete the form only once although they may have reviewed more than one paper during the period of the study.

One of the arguments against blinding is that the review process should be completely open, i.e., if the identity of authors is disclosed, reviewers, in turn, should be willing to sign their reviews. For this reason, persons who were not in favor of blind review were sent another questionnaire. They were asked whether they would like to receive the full face sheet containing the name and institution of the author on the manuscripts sent to them for review (yes/no/no preference) and, if yes, whether they intended then to sign their reviews (yes/no).

Results

The analyses are based on 305 fully completed and 7 partially completed returns (accounting for slight discrepancies in totals). There were no written refusals although 4 blank questionnaires were returned with a review. There were 78 pairs and three triplets (different reviewers for the same manuscript) among the returns. Thus the data reflect responses of 312 reviewers to 228 manuscripts.

There were responses to 614 potential chances to identify author or institution, 286 (47%) of which were taken. Overall 84% of the responses taken correctly identified author or institution (Table 1). "Maybe" responses were less likely than "yes" responses to be correct, but only 25% of the "maybe" responses were incorrect. Author and institution were identified correctly to the same extent even when responses were disaggregated (Table 2). Thus blinding could be considered successful 53% or 61% of the time, depending on whether successful blinding ignores identification or includes only correct identification.

Among those reviewing the same manuscript there was agreement in 108 (90%) of the 120 chances taken in common; in 11 of the 120 chances the agreement consisted of an incorrect identification by both respondents.

Self-referencing (61.8%) and personal knowledge (38.2%) were the two clues given for identification of author and/or institution. In both cases 16% of the identifications were incorrect. Clues given and incorrect identifications were unrelated to opinions concerning blind review.

Overall, blinding was favored by 75% of the respondents with 8% stating they had no preference. The 17% initially opposed to blind review is reduced to 11%, and the proportion with no preference increased to 14% when the follow-up of those opposed to blind review is considered.

The principal reason given for their opinion by those favoring blind review was the elimination of bias (Table 3). The principal reason given for their opinion by those opposing blind review was failure of the attempt to blind (in 2 out of the 14 chances taken by this group, identification was incorrect). Two other reasons concerned with the effect of knowing author identity on the review itself appear to contradict each other.

Of 30 reviewers initially opposed to blind review who, on follow-up, expressed an interest in receiving the manuscript face sheet, only 8 stated they would sign all their reviews; 19 indicated they would not do so, and 3 would do so only in some cases.

Discussion

Blinding of this group of reviewers was somewhat less successful than has been reported by others,[6,11] perhaps because self-referencing was more common. Moreover, in the type of population studies published by *AJPH,* the text must identify the source of the data. However, self-referencing that yields an unfamiliar name may mean nothing to a reviewer. Many reviewers noted that although self-referencing gave away the name, they were unfamiliar with the authors or their work. If all 82 responses that mentioned only self-reference are eliminated, blinding of author could be considered success-

*Ninety-six respondents (31%) gave no reason for opinion.

ful, whether or not identification was correct, 83% of the time. Many reviewers who favored blind review commented that they could often identify the author.

It is possible that the long-standing blind review policy of the *AJPH* may have influenced the opinion of our reviewers. However, as reported elsewhere,[13] the vast majority of these reviewers also review for many other journals, most of which do not have such a blind review policy.

All reports of the success of manuscript blinding reflect a Hawthorne effect whose impact is unknown: reviewers may seek out author and institutional identity more vigorously than in their usual review because the question is asked. Evidence for this constraint on the interpretation of these data can be found in this study: in 11 of the 120 chances taken in common, 1 reviewer identified author and/or institution correctly, giving as the reason self-reference, whereas the other reviewer of the same manuscript claimed to be unable to make any identification.

Most of those opposed to blind review would not sign their reviews, throwing doubt on the feasibility of a truly "open" review process. As an editor I, too, would be opposed to having the reviewers sign their reviews because their signing would intrude a third person into the decision process. Those who favored blind review were not asked whether they would sign their reviews.

This survey was not designed to assess the effect of blinding on the content of the review or the reviewers' recommendations to the editor. Nevertheless, the findings can be interpreted as evidence both for and against blinding. Against blinding is the fact that in about half the manuscripts some identification was claimed. Thus if identification biases the reviewer, it does so for some authors but not for others, affecting the equity of the review process; an appreciable number of cases may be falsely identified. In favor of blinding is the fact that a small number of reviewers opposed to blind review apparently felt that the track record and background of authors were factors that could influence their judgment about a paper. This may be reasonable for the rare opinion piece, but it implies a possible bias in the case of a research paper that should be judged solely on its merits.

The vast majority of *AJPH* reviewers favoring blind review contrasts with a recent report of a reader survey of the Federation of American Societies for Experimental Biology (FASEB) journal; most of the respondents were also reviewers (Lew Gidez, personal communication). Response rate for this survey was 45%, but there were 871 respondents. Half of the respondents were opposed to blind review compared with 17% or less of the *AJPH* reviewers. One can only speculate about reasons for this difference of opinion; the fact that the *FASEB J* reviewers are closer to the physical sciences and that *AJPH* reviewers are closer to the social sciences may account for some of this difference.

Although blind review may produce a somewhat kinder and more complete review,[11] I doubt that it can remove bias where negative or positive reviewer bias is associated with reviewer knowledge of author identity. I believe one must rely on the reviewers themselves to be frank about their own biases. Many reviewers return papers with a note recusing themselves for a variety of reasons. Moreover, it is the editor, not the reviewer, who makes the decision on a manuscript, and the editor cannot be blinded.

The fact that the majority of *AJPH* reviewers prefer to continue the blind review policy seems sufficient reason to continue it. Until more definitive data are in, reviewer preference, which differs from journal to journal, seems the most legitimate guide to the policy of journals on blind review. ☐

Acknowledgments

The author thanks the many reviewers who took the time and trouble to respond so fully to the questionnaire they received.

Tobacco Smoking as a Risk Factor for Colon Polyps

Shelia Hoar Zahm, ScD, Pierluigi Cocco, MD, and Aaron Blair, PhD

ABSTRACT

Background: Data from a cancer screening project among pattern workers were used to evaluate the association between tobacco smoking and prevalence of colon polyps.

Methods: From 1981–1983, 549 White men were examined by flexible sigmoidoscopy and completed self-administered questionnaires including smoking histories.

Results: One or more colon polyps were detected in 76 men. Standardized prevalence rates (SPR) for polyps increased by smoking category (never smoked = 0.094; ex-smokers = 0.118, current smokers = 0.214) and by cigarettes per day, years of smoking, and pack-years among both current and ex-smokers. Both adenomatous and hyperplastic polyps showed an association with smoking while other types of polyps and polyps with unspecified histology did not. The risk associated with smoking was greater for polyps greater than one centimeter in diameter. An interaction with occupational exposures was suggested by a greater increase in the SPR for polyps among current smokers employed as pattern makers for more than 10 years than among current smokers similarly employed for 10 years or less.

Conclusions: Since at least some colon polyps are considered precursor lesions to colon cancer, one of the most common cancers in the United States, this report suggests that the possible link between colon polyps and smoking deserves further evaluation. (*Am J Public Health*. 1991; 81:846–849)

Introduction

Most epidemiologic studies of colon cancer have suggested that there is no strong or moderate elevation in risk of cancer of the colon among smokers. [1,2] Whether there is a slight increase in risk, perhaps limited to a subgroup of susceptible people, is not known, although some recent work suggests this possibility.[3–6] In addition, an association has been noted between smoking and the presence of adenomas and hyperplastic polyps of the colon in men and women.[7,8] Since adenomatous polyps are known to be precursors of colon cancer,[9] the possibility that smoking influences the development of colon polyps deserves further evaluation. The availability of the data from a colon cancer screening project among pattern makers allowed us to evaluate the association between tobacco smoking and prevalence of colon polyps.

Methods

Pattern makers construct prototypes for mass-produced items, such as automobiles and agricultural implements. They can be exposed to wood, metals, fiberglass, plastics, epoxy resins, welding or soldering fumes, cutting oils, solvents, and spray paints. Three partially overlapping epidemiologic studies reported excess colorectal cancer in pattern makers[10–12] and led to cancer screening programs of pattern makers employed by General Motors Corporation and Ford Motor Company[13] and of members of the Pattern Makers League of North America who worked independently or for other corporations.[13] Data from the screening program of the non-General Motors members of the Pattern Makers League employed other than at General Motors Corporation or Ford Motor Company are the subject of this report. The background of this project has been described in more detail elsewhere.[14,15]

From 1981 through 1983, 1,465 White men from 16 factories were examined by flexible sigmoidoscopy and completed a self-administered questionnaire collecting information on sex, age, race, marital status, education, cancer symptoms, respiratory function, medical history, occupational history, and a few dietary constituents including alcohol but not total fat. The participation rate was 48 percent, a low rate due in part to the economic depression that affected the United States automotive industry during the screening program.[12] The unemployment rate among League members rose from 3 percent to 53 percent during the program with many unemployed pattern makers becoming ineligible for the medical insurance coverage that supported the screening.

Men from 11 of the factories (N = 549) also provided smoking histories and form the basis of this report. There is no evidence that the smoking histories, exposures, or polyp rate of the men at the remaining five factories where the workers did not provide smoking histories differed from that at the 11 other factories. The participation rates at the 11 factories where workers provided smoking histo-

ries (47 percent) and at the remaining five factories (50 percent) were similar. The age, duration of employment, employment status (e.g. active, inactive, and retired), and screening diagnoses of the study subjects are presented in Table 1.

The screening program identified three men with colon cancer, 76 men with one or more colon polyps, 54 men with other gastrointestinal disease, and 411 men with no evidence of any gastrointestinal disease. Five men had unknown sigmoidoscope results. Thirty-one of the 76 polyp cases had adenomatous polyps, 24 had hyperplastic polyps, and the remainder had other or not otherwise specified polyps.

Cigarettes per day, years of smoking and pack-years were used as indices of exposure to tobacco smoking for each current or ex-smoker. Three men without colon cancer or polyps had unknown smoking histories and were excluded from the analyses. Several subjects had incomplete smoking histories (e.g. ex-smokers with unknown number of cigarettes per day) and were excluded from some analyses when necessary.

We computed standardized prevalence rates (SPRs) for each category of smoking habit, adjusted for age (< = 40 years, 41–55 years, and 56+ years) and alcohol use (daily consumption of beer, wine, or hard liquor: no, yes, unknown), using the age and alcohol distribution of the entire study population participating in the screening as the standard. Smaller categories of age were not necessary for adequate adjustment for age. The measure of association was the risk ratio (RR). Maximum likelihood estimates, adjusted for the age and alcohol distribution of the smokers and the non-smokers among the men from the 11 factories who provided smoking histories, 95 percent confidence intervals (CI), and Chi tests for trend were obtained using EPITOME, personal computer statistical software under development by the Epidemiologic Methods Section, Biometry Branch, of the National Cancer Institute.[16]

Results

The age- and alcohol-adjusted prevalence rate for colon polyps among men who had ever smoked (0.150) was significantly higher than the rate among nonsmokers (0.094) (RR = 1.7, CI = 1.0, 2.9) (Table 2). The prevalence rose by smoking category (ex-smokers = 0.118; current smokers = 0.214; p for trend = 0.008) and by average number of cigarettes per day, years of cigarette smoking, and pack-years among ex-smokers. The increases in cigarettes per day, years, and pack-years of smoking were also significant, but less consistent, among current smokers.

Comparing current smokers to men who never smoked, risks for adenomatous (RR = 2.7, CI = 1.0, 7.1) and hyperplastic polyps (RR = 3.0, CI = 1.0, 8.7) were higher than risk for other or not specified polyps (RR = 1.0, CI = 0.3, 4.1) (Table 3).

The relative risk for smoking also varied by size and number of polyps. Among current smokers, the RR for polyps less than 1.0 centimeter in diameter was 1.5 (CI = 0.7, 3.1) in comparison with a RR of 2.6 (CI = 1.0, 7.0) for larger polyps. Men who never smoked and ex-smokers were at greater risk for only one polyp than for two or more polyps. Among current smokers, the RR was similar for only one (RR = 1.5) and more than one polyp (RR = 1.6).

Among current smokers, risk for polyps was greater in men employed as pattern makers for more than 10 years (RR = 3.0, CI = 1.3, 7.0) than in men employed 10 or fewer years (RR = 1.4, CI = 0.7, 2.9) (Table 4). Greater risks of polyps among the smokers employed more than 10 years were observed at almost all levels of smoking intensity and duration in comparison to the smokers employed 10 or less years. The higher risks in the longer employed workers were not due to a disproportionate number of heavy or long-term smokers in the group in comparison to the smokers employed 10 or less years. There was little difference by duration of employment among men who never smoked or were ex-smokers.

Discussion

The results presented in this report support the previous findings[7,8] of an association between tobacco smoking and risk of colon polyps. Risk increased significantly and consistently with smoking history category, cigarettes per day, years of smoking, pack-years, and diameter of polyps. Smoking increased the risk for hyperplastic and adenomatous polyps, which are considered the primary precursor lesions of colon carcinoma,[1,9,17] more than the risk for other histologic types. The risk of colon polyps among current smokers was greater in men employed as pattern makers more than 10 years than in men employed for shorter periods of time.

Cigarette smoking is known to be strongly associated with coffee consumption[18] and may be associated with other dietary factors, such as fat intake[18] and alcohol consumption,[19–21] which influence the development of colon polyps and cancer. Analyses were adjusted for age and alcohol consumption, but detailed dietary histories were not available in this study to evaluate other possible confounders. Even the adjustment for alcohol, based on only a crude classification, may have been inadequate to completely account for its possible confounding.

The present study was based on prevalent colon polyps detected in a screening program. Because prevalence reflects incidence and duration, it is not clear if the association with smoking is related to duration, rather than incidence, of colon polyps. The increase of risk with the diameter of polyps is consistent with an association with duration; however, differences in growth rates may be responsible. In addition, risk of multiple polyps was not greater than risk of single polyps among smokers.

No information is available on previous colonoscopies among the study subjects; however, the subjects were asked whether a doctor had ever told them they "had a polyp (growth) in the large intestine (colon, rectum, bowel)." The same percentage of smokers (4 percent) and nonsmokers (4 percent) reported a previous diagnosis of polyp. Therefore, there is

no evidence that the nonsmokers had more previous diagnostic tests or polypectomies than the smokers. The lower prevalence of polyps observed in nonsmokers in the current screening program does not appear related to differences by smoking status in participation in previous screening programs.

It is difficult to determine if pattern makers as a group have an increased prevalence of colon polyps in comparison to the general population. There are few published reports on the results of colon screening among asymptomatic subjects using flexible sigmoidoscopy. Most reports are based on subjects presenting with symptoms for a gastroenterology evaluation and, until recently, used the shorter rigid sigmoidoscope. Age-specific prevalence data and information on the size of the polyps detected are necessary for unbiased comparisons since the prevalence of polyps increases dramatically with age and the minimum diameter of reported polyps affects prevalence estimates. An earlier report on this population of pattern makers[14] concluded that the prevalence of polyps was not excessive in comparison with four other asymptomatic populations screened by flexible sigmoidoscopy. Another evaluation of pattern makers,[22] which included some of the same subjects as the Hoar, *et al*, report,[14] concluded there was an excess of polyps in the pattern makers; however, the polyp size may not have been considered adequately.

The observed association between smoking and colon polyps, in particular adenomatous polyps whose progression to cancer has been reported,[9,17,21] suggest that colon cancer may also be affected by use of this product. Colon cancer is not generally considered a tobacco-related malignancy; however, the literature is inconsistent. Most published studies of colon cancer have not provided information on smoking. Slight deficits of colorectal cancer among smokers have been reported in the American Cancer Society survey,[23] the Third National Cancer Survey,[19] and a recent study from Italy.[24] A significant inverse association has been reported among women by Sandler, *et al*,[3] which, they speculate, may be due to an antiestrogenic effect of smoking. On the other hand, Sandler, *et al*,[3] reported an increased rate of colon cancer in male smokers ages 25–44, (nonsmokers and passive smokers: 5.5/100,000 ; ever smokers: 19.0/100,000). Slight excesses of colorectal cancer occurred among male British doctors,[4] US veterans,[5] and, for rectal cancer, female British doctors.[6]

Not all colon polyps result in colon cancer. Although some polyps are considered precancerous lesions, some of them disappeared in a follow-up study.[25] The risk factors for colon cancer and polyps may differ or act with different strength.[26] Smoking may interact with other factors, as suggested in this study by the higher risk of polyps in long-term employees.

[*] Reference category for all comparisons is the men who never smoked and were employed as pattern makers for ≤10 years.

[+] 95% confidence interval, adjusted for age and alcohol.

An explanation for the findings of an association between colon polyps and smoking and the inconsistent relationship between smoking and colon cancer in the published literature is not entirely apparent to us but, may be due to population variations in the distribution of non-, ex-, and current smokers and in the percent of colon cancers with adenomatous polyp precursors. In the current study, there were 185 nonsmokers, 229 ex-smokers, and 132 current smokers whose risk ratios for adenomatous polyps were 1.0, 1.2, and 2.7, respectively. Previous reports in the literature suggest that approximately 30 percent of colon cancers have adenomatous polyp precursors.[27,28] Assuming that this 30 percent has the same smoking distribution and risks as the adenomatous polyp cases and that the remaining 70 percent of colon cancer cases have no risk associated with smoking (risk ratio = 1.0), a weighted overall risk estimate would be 1.15. Slight changes in any of these parameters would result in the inconsistent overall risk estimates for colon cancer and smoking observed in literature, particularly in the presence of residual confounding by dietary and other risk factors. Given the high incidence of colon cancer in the United States, the association deserves further evaluation. ☐

Passive Smoking During the First Year of Life

Robert A. Greenberg, MD, MSPH, Karl E. Bauman, PhD, Victor J. Strecher, PhD, MPH, Lynette L. Keyes, MS, MPH, Lucinda H. Glover, MPH, Nancy J. Haley, PhD, Helen C. Stedman, BS, and Frank A. Loda, MD

ABSTRACT

Background and Purpose: A description of passive smoking during the first year of life might assist planning preventive efforts.

Methods: Changes in the ecology of passive smoking were investigated in a sample of infants in central North Carolina followed from birth to one year of age.

Results: The prevalence of tobacco smoke absorption, indicated by excretion of cotinine, increased from 53 percent to 77 percent (95% CI of difference: 14, 35) during the first year of life. Most infants (92 percent) excreting cotinine at three weeks of age were also excreting it at one year. Moreover, 61 percent of infants not excreting cotinine at age three weeks were excreting it at one year. This increase reflected an increased exposure to household and, particularly, nonhousehold sources of smoke; the proportion of infants exposed to nonhousehold smokers increased from 14 percent to 36 percent.

Conclusions: These findings suggest that prevention of the onset of passive smoking should begin very early. (*Am J Public Health.* 1991; 81:850-853)

Introduction

Recognition of the adverse health effects of passive smoking in childhood, particularly during the first year of life,[1-3] has led to efforts to reduce exposure to environmental tobacco smoke.[4] To better inform such efforts, we previously reported the frequency of passive smoking and the circumstances in which it occurred in healthy neonates in central North Carolina.[5] The observations from that research were extended by a one year follow-up of a sample of the original study infants. This paper reports the changes in tobacco smoke exposure and absorption during the first year of life, identifies selected correlates of these changes, and considers the implications of findings for prevention of passive smoking during infancy.

Methods

Study Population

The infants were enrolled at birth, from April 1986 to May 1987, in an experimental study of a program to reduce passive smoking and respiratory illness. To be eligible for enrollment, an infant had to have no significant postnatal problems, a birth weight of at least 2,000 gm, and reside in Alamance County or Chatham County in central North Carolina. Infants in the previous neonatal study[5] were recruited from three hospitals where 433 mothers (40 percent of the 1,096 eligible) gave informed consent. Following data collection for those 433 infants, 216 infants began the passive smoking reduction program to which they had been randomly assigned and 217 remained in the control group. Sixty-five infants in the control group were lost to follow-up by one year of age. The remainder of the control group (n = 152) constituted the study sample for the present paper.

The mean number of adults living in study households was 2.3 at both enrollment and at one year. Seventy-five percent of the infants were living in two-parent families as neonates and 70 percent at one year.

Table 1 describes the study sample. There were no significant differences between the 152 infants in the study sample and the remainder of the 1,096 infants who were eligible for enrollment in the gender of the infant, mother's age, mother's race, and smoking by the mother. The study population, however, included significantly more heads of household with more than a high school education (45 percent) than the remainder of the eligible population (34 percent).

Data Collection Procedures

Data collectors visited the homes of enrolled infants when the infants were approximately three weeks of age [mean age (SD): 18 (seven) days, range: nine to 51 days] and before the family's assignment in the intervention trial. The follow-up visit for the data reported in this study was when the infants were approximately one year old [mean age (SD): 12.3 (0.6)

months, range: 11.5 to 14.9 months]. Before beginning the interview, the data collector placed a urine collection bag on the infant and explained to the mother that the urine would be analyzed for tobacco smoke products to determine whether the baby had been exposed to smoke. The mother was then asked to describe the smoking habits of all household members and any recent exposure of the infant to tobacco smoke.

Definitions of Variables

An infant was considered to have *contact with smokers* if the infant lived in the same household as a smoker or was in the same place, at the same time, as a nonhousehold smoker, either in the house or elsewhere. A smoker was anyone who smoked at least one cigarette, cigar, or pipeful per day.

Exposure to tobacco smoke was considered to occur when smoke was produced in the infant's presence, that is, in the same room or vehicle as the infant. The amount of exposure was expressed as cigarettes per week smoked in the infant's presence. (See Appendix for method of measurement.)

Smoke absorption was defined as sufficient airway contact with tobacco smoke to result in absorption of nicotine. It was measured by the urinary concentration of cotinine, a major metabolite of nicotine.[2]

Urine cotinine and our questionnaire measure of tobacco smoke exposure are related, but different measures of passive smoking. We have reported analyses of this relationship in infants elsewhere.[5,6] (See Appendix for further discussion of measures of passive smoking.)

Laboratory Procedures

The urine samples were frozen and shipped to the American Health Foundation, in Valhalla, NY. Researchers there analyzed each specimen without knowing the exposure status of the infant.

Cotinine concentration was quantitated by radioimmunoassay with a modification of the method originally described by Langone, *et al.*[7] This protocol uses specific antisera produced by rabbits and has interassay and intraassay variations of 8 percent, with a sensitivity of 1 ng/ml (6 nmol/L). Levels less than 2 ng/ml (12 nmol/L) were reported as below limits of reliable detection.

Creatinine was measured by dry chemistry methods on a Kodak Ektachem 400 analyzer (Eastman Kodak Company, Rochester, NY). The cotinine was divided by the creatinine concentration to adjust the data to reflect the concentration of the urine sample.

TABLE 2—Sources of Exposure to Tobacco Smoke

	Percent of Infants (N = 152)			
Source of Exposure	3 weeks %	1 year %	% Difference (95% CI)	% Change
Any source	39	63	23[a] (14, 32)	+62[a]
Mother	18	29	11 (5, 16)	+61
Nonmaternal household members	24	35	11 (4, 19)	+46
Nonhousehold smokers	14	36	22 (12, 31)	+157
More than one source	15	33	18 (10, 26)	+120

[a] Because of rounding, number does not exactly equal calculations made from table.

Infants of the nine mothers who smoked and breast-fed were eliminated from all analyses that used cotinine as a continuous variable because of the large amount of nicotine and cotinine absorbed through breast-feeding, relative to the amount absorbed through the airways.[8]

Statistical Methods

Distributions of categorical variables were compared by the chi-square statistic or the Fisher's Exact Test. The two-tailed Student t statistic was used to compare means of continuous variables for two groups.

McNemar's test was used to assess changes between three weeks and one year of age in the proportion of infants exposed to tobacco smoke from different sources and the proportion excreting cotinine.

Analyses of cotinine comparing smoke absorption at the two ages involved only the 114 infants who provided urine specimens at both data collection visits.

Results

Exposure to Tobacco Smoke

Between three weeks and one year of age, the proportion of infants reportedly exposed to tobacco smoke from any source increased from 39 percent to 63 percent (Table 2). The proportion of infants exposed to tobacco smoke produced by their mothers, by nonmaternal household members, by nonhousehold smokers, and by more than one of these sources, increased significantly during the first year of life. The greatest increase (157 percent) was in the proportion of infants exposed to smoke produced by nonhousehold smokers. Very similar results were found when the data analyses for Table 2 were repeated for just the 114 infants who provided urine specimens for cotinine analysis.

One infant was in day care at 3 weeks of age. By one year, 90 (58 percent) of the 152 study infants were in day care and 17 (19 percent) of those in day care were exposed there. Only six infants had their only exposure in day care.

The median amount of exposure for the 39 percent of infants who were exposed to any source of smoke at three weeks was 36 cigarettes per week per infant, with a range from two to 250 cigarettes per week. When these exposed three-week-old infants became one-year-olds the median amount of exposure was still 36 and the range was zero to 343 cigarettes per week.

TABLE 3—Distribution of Infants by Smoke Absorption Status at Age One Year Based on Status at Age 3 Weeks (N = 114[a])

	Smoke Absorption Status	
	Age 3 weeks (N)	Age 1 year (N)
Cotinine in urine	+(60)	+(55) 92% − (5) 8%
No cotinine in urine	−(54)	−(21) 39% +(33) 61%

[a]Infants who provided urine samples at both ages.

Among exposed three-week-old infants, the mother contributed, on the average, 34 percent of the cigarettes per week to which an infant was exposed. All household members other than the mother contributed 42 percent and nonhousehold smokers contributed, on the average, 23 percent to the total amount of an infant's exposure. Among exposed one-year-old infants, the mother contributed, on the average, 33 percent; nonmaternal household members, 38 percent; and nonhousehold smokers, 28 percent.

Absorption of Tobacco Smoke

At three weeks of age, 53 percent of the infants had cotinine in their urine. By one year, the proportion excreting cotinine increased to 77 percent (95% CI of difference: 14, 35).

For the infants excreting cotinine at three weeks, the median cotinine concentration was 79 ng/mg of creatinine (51 nmol/mmol) with a range of 9–643 ng/mg (6–413 nmol/mmol). The median among the same infants at one year was 127 ng/mg of creatinine (82 nmol/mmol), range 0–714 ng/mg (0–458 nmol/mmol). Among individual infants, the difference between the urine concentrations at the two ages varied considerably. Although the mean difference was only 11 ng/mg of creatinine (7 nmol/mmol), the 95% CI of the difference was wide: −40 ng/mg (−26 nmol/mmol), 62 ng/mg (40 nmol/mmol).

Table 3 contains the distribution of infants by smoke absorption status at one year, according to smoke absorption status at three weeks. Almost all infants (92 percent) absorbing tobacco smoke at three weeks were also absorbing smoke at one year. In contrast, only 39 percent of infants who were not absorbing smoke at three weeks were still not absorbing smoke at one year. We compared the characteristics of these 21 infants with the 33 infants who also were not absorbing smoke at three weeks, but who became tobacco smoke absorbers by one year. The latter infants were more likely to live in a household with smokers, 30 percent compared with only 5 percent of infants who continued to not absorb smoke at one year. The two groups of infants did not differ by educational level of the head of household, race, or the proportion attending day care at one year.

Discussion

Although passive smoking was already common at three weeks of age, there was a large increase in the prevalence of passive smoking by one year, an increase found in both the proportion of infants exposed to smoke and in the proportion absorbing nicotine. The large number of infants eligible for enrollment who were not in the study sample may limit the generalizability of our results. For example, because the heads of household of infants not included in the study had less education and were therefore more likely to smoke, the extent of passive smoking among study infants may be an underestimate for infants in the entire community.

Our analysis of smoking by household members suggests that the increase in prevalence of passive smoking might be reduced by urging smokers who are already in contact with infants, but not smoking in their presence, to continue to refrain after the newborn period. Considering the large increase during the first year of life in the proportion of infants exposed to smoke produced by nonhousehold smokers, parents should be encouraged to limit contact between their infants and nonhousehold smokers. Mothers may be unaware of all contacts their infants have with smokers, however: 24 percent of the three-week-old and 49 percent of the one-year-old infants in our study were reported to have no contact with smokers but had cotinine in their urine.

Our findings support vigorous early and continued efforts to prevent infant passive smoking. The larger study from which the data reported here are derived is evaluating one such effort.[9] □

Acknowledgments

This research was funded by Grant No. 28895 from the National Heart, Lung, and Blood Institute, National Institutes of Health.

We are grateful to the pediatricians of Alamance County and Chatham County, North Carolina, for supporting our study of their patients. The cooperation of the administrative and nursing staff of Alamance County Hospital, Alamance Memorial Hospital, and North Carolina Memorial Hospital is also greatly appreciated. We thank the staff of the Infant Health Study, whose work made this study possible.

APPENDIX

Measures of Passive Smoking

Data to measure exposure to tobacco smoke were gathered for both "a typical day last week" and "during the last weekend." The mother identified all the places where the infant spent time, including rooms in the house, at other homes, in cars, and in other places outside the home. For each place, the mother reported all smokers who entered while the infant was there. She also reported whether they smoked, as well as what, and how much they smoked. The amount of exposure was calculated by multiplying the number of cigarettes smoked in the infant's presence during "a typical day" of the previous week by five, and adding the number of cigarettes smoked in the infant's presence during the previous weekend. A cigar or pipeful was considered equivalent to one cigarette. Infants who were cared for more than four hours a week away from their home were defined as in day care. If the mother reported that the day-care workers smoked inside where the children were, then the infants were considered exposed to tobacco smoke. The amount of exposure in day care was not determined.

Both the interview measure of exposure to tobacco smoke and urine cotinine were used as measures of passive smoking because of their different strengths and limitations.[6,10] The interview measure estimates the amount, source, and location of exposure during the previous week, taking into account potentially different smoking habits during the week and the weekend. (We requested a report of exposure during a "typical" weekday because we were interested in a reflection of chronic exposure that was not influenced by unusual experiences during the previous week. However, a possible limitation of using only a "typical" weekday is that exposure in some infants may vary considerably from weekday to weekday.) The questionnaire results are limited by being subject to the memory of the mother and to biased reporting.

The presence of cotinine in urine is an accurate indication that nicotine has been absorbed during the 48 to 72 hours prior to specimen collection, but provides no information about the exposure leading to absorption or about past absorption. The concentration of urine cotinine varies considerably among those exposed to the same amount of nicotine,[11] and the possibility of differences in the same infant at different ages in the pharmacokinetics and metabolism of nicotine remains to be explored. Also, nicotine is only one of thousands of compounds in tobacco smoke and is probably not responsible for the health effects of passive smoking.[1]

Among the study infants who provided urine specimens at three weeks and one year of age, we found the following relationships between exposure to tobacco smoke (cigarettes per week smoked near the infant) and absorption of nicotine (urine cotinine concentration). The Spearman rank correlation at three weeks was 0.50 (95% CI: 0.35, 0.63) and at one year, 0.68 (95% CI: 0.56, 0.77). Among the 60 infants excreting cotinine at three weeks, 60 percent were reportedly exposed during the previous week; whereas among the 54 infants with no cotinine in their urine at three weeks, 20 percent were exposed. Among the 88 infants excreting cotinine at one year of age, 69 percent were exposed during the previous week; whereas among the 26 infants not excreting cotinine at one year, 27 percent were exposed.

Are the Correlates of Cigarette Smoking Initiation Different for Black and White Adolescents?

ABSTRACT

Background: Studies of adolescent smoking suggest that the causes of smoking initiation may differ for Blacks and Whites.

Methods: Correlates of smoking initiation were examined among 1,277 nonsmokers, ages 12–14, who completed questionnaires in their homes. The analyses examined relationships between smoking initiation and 11 explanatory variables using logistic regression with the combined sample and with Black and White samples.

Results: Over two years, 24 percent of Whites and 14 percent of Blacks started to smoke. Whites were more likely to start smoking at age 12 and Blacks at age 14. Having a best friend who smoked increased the odds of initiating smoking over twofold for Whites but had no effect on the odds of smoking for Blacks.

Conclusions: Whites initiate smoking earlier than Blacks and are more likely to be influenced by friend behavior. (*Am J Public Health*. 1991; 81:854–858)

Sandra W. Headen, PhD, Karl E. Bauman, PhD, Glenn D. Deane, MA, and Gary G. Koch, PhD

Introduction

Most research on adolescent smoking has involved only White subjects or has not reported findings separately for Blacks and Whites.[1–9] The findings of these studies typically have been applied to both races, but this practice may lead to erroneous conclusions about the behavior of Blacks. The several studies that compared Blacks and Whites found both similar and different correlates of smoking. For example, smoking initiation by both Blacks and Whites has been linked to age, smoking by siblings and friends, perceived availability of cigarettes, intentions to smoke, and ease of refusing cigarettes; risk-taking has been associated with smoking for Blacks but not Whites; parental smoking has been correlated with smoking for Whites but not Blacks.[10–12] Correlates of regular smoking also differed for Black and White samples suggesting that the causes of smoking for these groups differ as well.[13]

This study examines whether the correlates and therefore possible causes of adolescent smoking are the same for Blacks and Whites. The correlates of smoking initiation are first examined for combined samples, testing for the effects of race, then examined separately for Black and White samples.

Methods

Sampling and Survey Procedures

The data are from a field experiment conducted to evaluate the influence of a mass media campaign on the onset of adolescent cigarette smoking. The campaign and its effectiveness are described elsewhere.[14,15] Ten of the 81 Standard Metropolitan Statistical Areas (SMSAs) in the southeastern United States that were similar on social and demographic characteristics and located in nonoverlapping broadcast areas were selected for the experiment. Using cluster sampling procedures, approximately 80 clusters of households were randomly selected in each SMSA to yield an expected average of 224 eligible adolescents per SMSA. Baseline surveys, conducted from April 1 through October 13, 1985, included all eligible adolescents (ages 12–14) within each SMSA (N = 2,534). In the presence of a trained interviewer, adolescents completed self-administered questionnaires in their homes. Follow-up data were collected two years later. For these analyses, data are aggregated for the 10 SMSAs.

Measurement

Cigarette smoking was derived from a 13-category item that ranged from "I have never smoked" to "I smoke two or more packs per day." Adolescents who smoked at least "a few times in the past year" were considered smokers and adolescents who had not smoked in the past year including never smokers were considered nonsmokers. A binary variable rather than the full range was used because the distribution was skewed toward infrequent and light smoking. This defini-

Address reprint requests to Sandra W. Headen, PhD, Department of Health Behavior and Health Education, School of Public Health, University of North Carolina, Chapel Hill, NC 27599-7400. This paper, submitted to the Journal March 29, 1990, was revised and accepted for publication January 8, 1991.

tion of smoking is consistent with studies that focus on the first or second smoking experience among young adolescents who are experimenting with cigarettes.[4,5] To enhance the validity of self-reports of cigarette smoking, adolescents who completed questionnaires were told that they would be asked to provide aveolar breath and saliva samples to measure actual smoking behavior.[18,19]

Explanatory variables that had been identified as correlates of adolescent smoking in prior research were selected for study.[1,2,4,5,13,18-22] These variables are associated with the social learning and problem behavior theoretical perspectives and are described in the appendix.[7,10,11,21] Age, gender, and parent education were included as control variables. The following transformations were performed:

- Parental education, age, educational intentions, and availability of cigarettes were included as binary variables because the distribution of responses for their original categories were skewed.
- Religiosity, peer versus parental influence, parental permissiveness, and rebelliousness were included as continuous scales and derived by obtaining the means of several items. Closeness to mother and mother's approval of adolescent smoking were included in their original forms.

Analysis

To examine smoking initiation directly, only the 1,277 subjects from the 1985–87 panel who had not smoked within the year preceding 1985 were included in these analyses, eliminating the possible confounding effects of prior smoking behavior on 1987 measures.

Evaluation of correlates of adolescent smoking was primarily based on a logistic regression analysis that included race and 10 other explanatory variables as predictors of smoking initiation. This model was a simplification of another model that had included 15 explanatory variables. Four variables—intentions to smoke, parental permissiveness, mother's approval of adolescent smoking, and availability of cigarettes—were dropped from the earlier model. The −2 Log likelihood statistic showed that the explanatory capacity of the models that included and excluded these variables was similar. The number of subjects who indicated an intention to smoke at baseline was too small for reliable estimation of its effect. The remaining variables were included to examine whether rates of maternal smoking reported by Black adolescents may be associated with social environments characterized by parental leniency, easy access to cigarettes, and tolerance of adolescent smoking. The effects of these variables were expected to be relatively small and essentially no explanatory ability for them was confirmed after adjustment for other variables in the model.

This study reports findings of logistic regression analyses for Black and White samples that resulted from the following procedures. For the combined samples, stepwise procedures were used to identify significant two-way interactions among 11 explanatory variables. Significant interactions with race were of particular interest because of their implication of different relationships for Blacks and Whites. In a subsequent step, three-way interactions, including race and explanatory variables involved in significant two-way interactions, were also examined. Finally, the model that had been obtained on the combined samples was evaluated for the separate samples of Black and White adolescents. The significant interactions between race and the variables, friend smoking and age, in the equation for the combined samples provided the justification for these analyses.

Results

Subject Participation

Of the 2,534 adolescents who were eligible for study, 2,102 participated in 1985 and 1,637 participated in both 1985 and 1987. Among 429 subjects who were eligible but did not participate in 1985, 50.7 percent (n = 218) refused and 49.3 percent (n = 211) had moved from the area, could not be reached after multiple attempts, or were excluded for other reasons. Failure to locate subjects and missing information were the primary reasons for attrition by 1987. Other analyses of these data showed that subjects in the panel and those who failed to complete the follow-up questionnaire did not differ on the following dimensions: age, gender, educational intentions, religiosity, rebelliousness, participation in school activities, and parental closeness.[23] However, subjects lost to follow-up were more likely to be regular smokers at baseline than adolescents who participated at both data collection points (5.6 percent versus 3.1 percent, respectively).[15]

TABLE 2—Descriptive Statistics for Explanatory Variables (1985)

Variables	Means or Proportions		Difference (95% CI)
	Black	White	
Best friend smokes[a]	22.90%	26.90%	4.00 (3.94, 4.06)
Mother smokes[a]	40.70%	27.30%	13.35 (13.32, 13.38)
Religiosity[b]	2.40	2.30	.10 (.02, .18)
Rebelliousness[c]	.22	.23	.01 (−.05, .07)
Close to mother[d]	4.58	4.48	.10 (00, .20)
Peer/parent influence[e]	3.30	2.60	.70 (.58, .82)
Educational intentions[f]			
college impossible[g]	8.20%	2.20%	6.00 (5.96, 6.04)
college possible[h]	34.80%	24.50%	10.20 (10.10, 10.30)

Categories were:
a) 1 = smoker, 0 = nonsmoker;
b) 3 = religion important, 0 = religion unimportant;
c) 1 = rebellious, 0 = nonrebellious;
d) 5 = extremely close to mother, 1 = not at all close;
e) 4 = parents more important, 0 = peers more important;
f) distributions for reference category (college certain) were 57% and 73.3% for Blacks and Whites respectively;
g) 1 = college impossible, 0 = college certain;
h) 1 = college possible, 0 = college certain.

TABLE 3—Adjusted Odds Ratios (and 95% confidence intervals) for Logistic Regression of Explanatory Variables on Smoking Initiation

Variables	Adjusted Odds Ratios (95% CI)	
	Blacks (n = 401)	Whites (n = 876)
Best friend smokes[a]	1.05 (.53, 2.10)	2.44 (1.68, 3.53)
Mother smokes[a]	.01 (.00, .76)	.06 (.01, .59)
Religiosity	.83 (.56, 1.22)	.81 (.65, 1.01)
Rebelliousness	1.34 (.37, 4.85)	2.39 (1.17, 4.85)
Close to mother	.60 (.39, .92)	.76 (.59, .98)
Peer/parent influence	1.04 (.75, 1.45)	.80 (.68, .94)
Educational intentions[b]		
College impossible	2.10 (.79, 5.58)	1.73 (.60, 5.00)
College possible	1.25 (.63, 2.48)	1.40 (.95, 2.08)
Parent education[c]		
< High school	.87 (.31, 2.46)	.30 (.12, .75)
College graduate	1.27 (.54, 3.00)	.81 (.55, 1.20)
Age[d]		
13 years old	1.12 (.40, 3.10)	.51 (.31, .84)
14 years old	2.53 (1.14, 5.64)	.93 (.62, 1.40)
Gender[e]	1.17 (.58, 2.39)	.59 (.41, .85)
Race[f]		

High scores mean more of a quality or parents influential. Reference categories were:
a) nonsmoker,
b) college certain,
c) high school graduate,
d) 12 years old,
e) male,
f) white.
Model Chi square = 25.74, df = 16, ($p < .06$), and 100.43, df = 16, ($p < .001$) for Black and White samples respectively.

Racial Differences in Smoking Initiation

Associations among race, gender, and 1987 smoking status of subjects who were nonsmokers in 1985 were examined separately for 12, 13, and 14 year olds. The results, shown in Table 1, indicate that, with the exception of 13 year old females, more White than Black adolescents initiated smoking during this two-year period. Smoking initiation more than doubled with age among Black adolescents, but increased only slightly with age among White adolescents.

Black-White Differences in Explanatory Variables

Results shown in Table 2 reveal some notable differences between Black and White adolescents on the explanatory variables. More Blacks than Whites reported that their mother smokes, but fewer Blacks reported having a best friend who smokes. Also, Black adolescents considered parents more important influences than did White adolescents. The majority of adolescents were confident that college was in their future, although fewer Blacks then Whites thought so. More Blacks than Whites were tentative about college attendance (college possible) or reported that a college education would be impossible for them.

Correlates of Smoking Initiation

The results of logistic regression analyses for Black and White samples reveal the following main effects, shown in Table 3, and several interactions that are discussed later:

- Friend behavior was more strongly related to smoking initiation among White than among Black adolescents; the odds of smoking if a friend smoked were 2.44 times greater among White adolescents but did not increase among Black adolescents.
- The age of smoking initiation also differed for Blacks and Whites; compared with Blacks, Whites were more likely to start smoking at age 12; Blacks were more likely to start smoking at age 14 than at ages 12 or 13.

Significant interactions in these equations revealed several findings. For both Black and White samples the odds of initiating smoking if mother smoked were extremely small among adolescents who reported being distant from mother (.03 and .10 for Blacks and Whites, respectively) and approached unity among adolescents who reported being close to mother (1.02 and .98 for Blacks and Whites, respectively). Another finding was the difference in smoking initiation among White males and females from low versus higher socioeconomic backgrounds. The interaction between gender and parent education in the equation for the White sample indicated that when neither parent graduated high school, males were 3.53 times as likely as females to initiate smoking; when one parent completed high school or college, males were only .58 times as likely to initiate smoking compared with females.

Discussion

The results of this study reveal two important findings regarding racial differences in adolescent smoking initiation. The first is that friend smoking is related to smoking initiation among Whites but not among Blacks. This observation suggests that smoking prevention programs that focus on the attitudes and behaviors of peers may not be effective with Black adolescents.

The second important finding is that Whites initiated smoking earlier than Blacks, an observation that is consistent with results of other studies conducted in the southeastern United States.[10,11,18] This outcome suggests that smoking prevention programs should be implemented in elementary grades to deter smoking among Whites and should continue into middle school to prevent smoking initiation among Blacks.

The results of this study suggest that racial differences in adolescent smoking can be examined more effectively with stratified analyses; aggregating data for Blacks and Whites obscures differences between these groups. For example, equations for both Black and White samples showed that adolescents who felt close to their mothers did not initiate smoking if their mother smoked. Also, the differences in smoking initiation among males and females from low versus higher socioeconomic backgrounds were found for the White sample only.

Our results also show that smoking rates and sample sizes must be sufficiently large to detect meaningful relationships for the Black sample when stratified analysis is used. The small proportion of smokers among Black adolescents in this study (14 percent of Blacks smoked in 1987 compared with 25 percent of Whites) and the smaller size of the Black sample decreased the capacity of logistic regression to explain smoking among Blacks.

In summary, this study found that Black adolescents initiated smoking later than Whites and were not influenced by their friends to start smoking. These findings indicate the need for more research on how differences in correlates of adolescent smoking contribute to differences in smoking among Blacks and Whites. We suggest greater emphasis on identifying and testing models of adolescent smoking that consider distinctive cultural and environmental factors that shape the behavior of Black adolescents. □

APPENDIX

Explanatory Variables

Variable names and categories	Description and original form
Best friend smokes Mother smokes 0 = nonsmoker (category 1) 1 = nonsmoker (categories 2–5)	Cigarettes smoked per day; five-point scale from 1 = none to 5 = more than one pack per day
Intentions to smoke 0 = do not intend to smoke (categories 1–3) 1 = intend to smoke (categories 4, 5)	Probability of smoking in two years; five-point scale from 1 = sure I will not smoke to 5 = sure I will smoke
Availability of cigarettes 0 = hard to get (categories 1, 2) 1 = easy to get (categories 3, 4)	Ease of getting cigarettes; four-point scale from 1 = very hard to 4 = very easy
Mother's approval of adolescent smoking	How mother would feel if adolescent smoked; five-point scale from 1 = strongly disapprove to 5 = strongly approve
Educational intentions 1 0 = college certain (categories 4, 5) 1 = college impossible (category 1)	How likely is college? five-point scale from 1 = attendance, impossible to 5 = attendance certain
Educational intentions 2 0 = college certain (categories 4, 5) 1 = college possible (categories 2, 3)	(same as above)
Religiosity; four-point scale from 0 = religion not important, never go to services to 3 = religion important, services weekly	Derived from mean of two, four-point scales: religion important? 1 = not important to 4 = very important; how often services attended? 1 = never to 4 = once a week or more
Rebelliousness continuous variable; range 0, 1 0 = nonrebellious 1 = rebellious	Derived from mean of four binary items; 1 = yes, 2 = no; try to follow rules? break rules you disagree with? break rules for sake of it? break rule to prove a point?
Close to mother; five-point scale from 1 = not close to 5 = extremely close	Feel close to mother?
Peer/parent influence; five-point scale from 0 = friends more important to 4 = parents more important	Derived from two, five-point scales; who do you listen to when you have problems? who influences your behavior? from 1 = friends more often to 5 = parents more often (3 = friends/parents equally)
Parental permissiveness/independence; continuous scale, range 0, 1	Derived from mean of five binary items; 1 = yes, 2 = no; weekend curfew? choose own friends? choose own clothes? regular bedtime? say parents are strict?
Parent education 1 0 = high school graduate (categories 2, 3, 4) 1 = less than high school (category 1)	Highest grade of either parent; six-point scale from 1 = did not graduate from high school to 6 = more than four years of college
Parent education 2 0 = high school graduate (categories 2, 3, 4) 1 = college graduate or higher (categories 5, 6)	(same as above)

Health Behaviors, Risk Factors, and Health Indicators Associated with Cigarette Use in Mexican Americans: Results from the Hispanic HANES

David J. Lee, PhD, and Kyriakos S. Markides, PhD

ABSTRACT

Background: Cigarette smokers often engage in other, potentially deleterious, health behaviors. Such behaviors have not been well documented in Mexican American smokers.

Methods: Data from the Southwestern sample of the Hispanic Health and Nutrition Examination Survey (HHANES) were employed to investigate differences in health behaviors, risk factors and health indicators between cigarette smokers and nonsmokers among Mexican Americans. Differences between those smoking < 10 and 10 or more cigarettes per day were also examined by age group and gender.

Results: Positive associations between smoking status and heavy coffee and alcohol consumption were found across gender and age groups. Less consistent was the finding that smokers weighed less than nonsmokers. Lower systolic and diastolic blood pressures in middle-aged smokers, and higher levels of depressive symptomatology among smoking women were found. Those smoking 10 or more cigarettes per day were more likely to report heavy coffee consumption, with younger men reporting greater activity limitation due to poor health. Middle-aged men and women in the 10+ category were generally in better health than lighter smokers.

Conclusions: Modest associations between cigarette smoking, health behaviors and risk factors found in other studies were confirmed in this Mexican American population. Few significant associations between smoking and health status were noted. (*Am J Public Health.* 1991;81:859–864)

Introduction

Cigarette smoking is the leading cause of preventable mortality in the United States with approximately 390,000 deaths annually attributed to this health behavior.[1] The prevalence of smoking varies by age, gender, and ethnicity. Males have higher rates of smoking than do women although the gap in rates has narrowed in recent years.[2] Smoking rates climb dramatically in adolescence, peak in middle age, and decline in old age. Overall, smoking rates among Mexican American men are comparable to estimates for Black American males (44 versus 41 percent)[3,4] while rates for Mexican American women are comparable to Caucasian women (25 versus 27 percent).[3,4] However, the prevalence of heavy cigarette consumption is lower among both male and female Mexican Americans than in other ethnic groups.[5]

While much research has focused on basic epidemiologic relationships between smoking and health outcomes, some research has focused on the relation between smoking and other risk factors. The importance of this research is four-fold:

- smoking may interact with other risk factors producing synergistic increases in the risk of negative health outcomes[6];
- smokers attempting to quit often need to reduce exposure to other health behaviors (e.g. alcohol consumption) which prompt smoking behavior;
- smokers who engage in multiple negative health behaviors are less likely to successfully quit smoking[7];
- change in one health behavior may lead to concomitant reductions in other health behaviors.[8,9]

Much of this research has focused on interrelations between alcohol, cigarette, and caffeine use documenting modest associations among these psychoactive substances.[10] Cigarette consumption has also been found to positively correlate with cholesterol levels,[11] but paradoxically is associated with lower blood pressure in adults.[12,13] There is also an inverse relationship between smoking and obesity.[14]

Although cigarette smoking is correlated with a number of deleterious health outcomes,[15] both gender and aging differences can influence these associations.[16] Therefore it is important to examine these differences in different age and gender groups. In addition, because most individuals do not start smoking after the age of 25, associations between smoking status and health may be influenced by two factors: those who quit smoking due to poor health; and selective survival with those most vulnerable to smoking-related mortality dying during middle age.[17] Cross-sectional analyses often reveal that older smokers are in better health than nonsmokers.[18]

The purpose of this study is to examine health behavior, risk factor, and health indicator correlates of smoking in a representative sample of Mexican Americans. Because of important age and gender differences, these associations will be examined separately by gender and age groups.

Dr. Markides is with the Department of Preventive Medicine & Community Health, University of Texas Medical Branch, Galveston. This paper, submitted to the Journal July 24, 1990, was revised and accepted for publication January 23, 1991.

Methods

The data employed are from the Hispanic Health and Nutrition Examination Survey (HHANES) conducted during 1982–84 by the National Center for Health Statistics.[19] Our analysis is limited to Mexican American respondents from the southwestern states (Texas, New Mexico, Colorado, Arizona, and California). The HHANES employed a complex multistage sampling design that aimed at obtaining a representative sample of Mexican Americans in the southwest (as well as Cuban Americans in the Miami (Florida) area and Puerto Rican Americans in the New York City area) ages 6 months to 74 years. The sampling design employed assured a 97 percent representation of the Mexican origin population of the southwest as well as 84 percent of all persons of Mexican origin in the United States (for details on sampling procedures see Gonzalez).[20]

Our analysis is limited to persons ages 20 to 74. A total of 3,935 persons in this age group participated in the household interview, with 3,326 participating in the physical examination where data on body weight and height, blood pressure, cholesterol, alcohol consumption, and depression were collected.

Measures

Current smoking status was ascertained in all participants who indicated that they had smoked at least 100 cigarettes in their lifetime. Current smokers were asked how many cigarettes they smoked daily. Responses ranged from less than one to greater than 86 with the actual number recorded between these two extremes. The median number of cigarettes consumed in this sample was used to compare participants whose consumption was "moderate" (<10 cigarettes per day) and "immoderate" (≥10 cigarettes per day).

Measures of health behaviors and risk factors included *Heavy Coffee Consumers* (coded 1 for those consuming 4 or more cups per day, 0 for less than 4, collected during a three-month dietary recall interview); *Current Alcohol Consumer* (coded 1 for current alcohol consumer; 0 for abstainer); *Average Alcohol Consumption* (average number of drinks consumed weekly); *Body Mass Index* [weight (in kilograms) divided by the square of the height of the individual (in meters)[21]]; *Systolic* and *Diastolic Blood Pressure* (based on the average of two blood pressure assessments during the physicians's examination[22]) and serum *Cholesterol* (milligrams per deciliter of blood plasma).

Health indicators included in this analysis were Activity Limitation, Self-Rated Health, Physician's Assessment, and Depression. *Activity Limitation* was based on a series of questions regarding limitation in major activity (e.g. job, housework, etc.) because of an impairment or health problem. In addition to the above, persons 71 to 74 years of age were considered to have activity limitation if they needed the help of others with personal care needs or daily routine activities because of any impairment or health problem, (coded 1 for activity limitation, 0 for other). *Self-Rated Health* was based on a single item asking respondents to rate their health as excellent, very good, good, fair, or poor (coded 1 to 5). The *Physician's Assessment* also graded subjects on the same 1 to 5 scale for an overall assessment of health. *Depression* was measured by the Center for Epidemiologic Studies Depression (CES-D) Scale which has been widely used in community surveys and has been extensively validated,[23,24] including with Hispanic populations.[25,26] Internal consistency reliability for the scale with the current data was in excess of .85. Range of scores on the CES-D is 0–60 with higher scores indicative of greater symptomatology.

Analysis

All analyses were calculated separately for males and females in three age groups: 20–39; 40–59; 60–74 years. Due to small sample sizes examination of the smoking consumption groups (<10; 10+) were not undertaken in the 60–74 age group. Log linear and general linear modeling were used to compare mean and percent differences across smoking categories.[27] When age was significantly different across smoking status or level of consumption within these age and sex categories, age-adjusted means and percents were calculated. For continuously distributed variables this analytic approach paralleled that of multiple classification covariance analysis[28] while for dichotomous dependent variables it parallels binary multiple regression analysis.[29] Both approaches require that the covariant be homogeneous across categories of the independent variable. Significant interactions between the covariate and the factor indicate that age adjustment may produce misleading results. Therefore, interactions between age and smoking status and level of consumption were first run to confirm independence. (See Mendes de Leon and Markides[26] for further details on application of this approach).

Analyses were performed with adjustments for sample weights and design effects. The latter were necessary because the HHANES employed a complex multistage sampling design. Sample weights were normalized by multiplying the number of subjects in each group employed in the analysis with each respondent's weight divided by the sum of the weights for the group. Design effects were estimated using the Taylor Approximation method of the SESUDAAN program and were used to adjust variances in the analyses.[30]

Results

The prevalence of smoking and level of cigarette consumption (<10; 10+) by age group and gender is reported in Table 1. Males were more likely to be smokers ($\chi 2 = 89.17$, $p<.001$) and to smoke more cigarettes ($\chi^2 = 7.93$, $p<.01$) than females. Prevalence rates also varied by age group with the highest rates found in the middle aged group for both smoking status ($\chi^2 = 7.11$, $p<.05$) and amount of cigarette consumption ($\chi^2 = 9.11$, $p<.05$). The age group by gender status interactions were not significant indicating that the smokers did not disproportionately fall into specific age group and gender categories.

Table 2 presents frequencies and means for health behaviors, risk factors, and health indicators for young males (ages 20–39). Smokers were more likely to report current alcohol consumption, reported greater consumption of alcohol, were more likely to be heavy coffee consumers, and reported poorer self-rated health. Smokers consuming 10 or more cigarettes per day were more likely to be heavy coffee consumers and reported greater activity limitation than smokers consuming less than 10 cigarettes per day.

Table 3 presents frequencies and means for health behaviors, risk factors, and health indicators for young females. As with young males, female smokers were more likely to report current alcohol consumption and were heavier drinkers. Levels of depressive symptomatology were also significantly higher among smokers than non-smokers.

Females consuming 10 or more cigarettes per day, were significantly older than smokers consuming less than 10 cigarettes per day (29.82 versus 28.22). Therefore, after confirming no age by consumption status interactions, age-adjusted means were calculated. As can be seen in

TABLE 1—Prevalence of Smoking Status and Prevalence of Smokers Consuming 10 or More Cigarettes Per Day by Gender and Age Group

		Percent Smokers			Percent Smoking ≥10 Cigarettes/Day	
	N	Male	Female	N	Male	Female
Age Groups						
20–39	2163	42.5	24.2	704	51.5	46.6
40–60	1313	46.4	27.4	455	60.9	50.3
60–74	457	39.7	19.8	133	74.1	54.0

Note: Main effects for smoking status: Age: $\chi^2 = 7.11$; $p<.05$; Gender: $\chi^2 = 89.17$; $p<.001$; Interaction: $\chi^2 = .11$; p = n.s
Main effects for cigarette consumption: Age: $\chi^2 = 9.11$; $p<.05$; Gender: $\chi^2 = 7.93$, $p<.01$; Interaction: $\chi^2 = 2.02$, p = n.s

TABLE 2—Comparison of Nonsmokers and Smokers and Amount of Cigarette Consumption Across Health Behaviors, Risk Factors, and Health Indicators Among Young Men (ages 20–39)

	Smoking Status		Amount of Smoking	
	Nonsmokers (N = 445–586)	Smokers (N = 319–436)	<10/Day (N = 148–212)	≥10/Day (N = 170–221)
	Mean	Mean	Mean	Mean
Health Behaviors/Risk Factors				
% Heavy Coffee Consumers	3	6*	1	10***
% Current Alcohol Consumers	68	79**	81	78
Average Alcohol Consumption^ (Drinks/Week)	4.4	5.5**	5.4	5.7
Body Mass Index (kg/m^2)	26.0	25.3	25.4	25.2
Systolic Blood Pressure (mmHg)	117.6	118.3	118.6	117.8
Diastolic Blood Pressure (mmHg)	76.3	75.8	75.6	76.0
Cholesterol (mg/dl)	194.9	197.2	193.3	200.4
Health Indicators				
% with Activity Limitation	9	9	5	13**
Self-Related Health	2.6	2.9***	3.0	2.8
Physician's Assessment	1.4	1.4	1.4	1.4
CES-D Depression	6.3	7.1	6.8	7.3

Note: *$p<.05$; **$p<.01$; ***$p<.001$
^Based on current consumers only (N = 319 nonsmokers; N = 264 smokers; N = 126 <10 cigarettes/per day; N = 137 10+ cigarettes/per day smokers).

Table 3, there were no significant health behavior, risk factor, or health indicator differences between individuals in the two smoking categories.

Table 4 shows the middle-aged (40–59) male smokers were more likely to report greater levels of alcohol consumption, weighed less, reported poorer self-rated health, and had lower systolic and diastolic blood pressure. Smokers consuming 10 or more cigarettes per day had significantly lower diastolic blood pressure than smokers consuming less than 10 cigarettes per day.

Table 5 presents frequencies and means for health behaviors, risk factors, and health indicators for middle-aged females. Age adjustment of means was necessary for the smoking status analyses after determining that the mean age of the smoking group was significantly higher than the nonsmoking group (49.20 versus 48.00). There were no significant interactions between smoking status and age.

Smokers were more likely to be current alcohol consumers, heavy coffee consumers, weighed less, and had lower diastolic blood pressure. Smokers also reported greater depressive symptomatology than nonsmokers. Smokers consuming 10 or more cigarettes per day weighed less, reported better self-rated health and less activity limitation. Table 6 shows that older (60–74) male smokers were more likely to report current alcohol consumption, were more likely to be heavy coffee consumers, and weighed less. Older female smokers were more likely to report current alcohol consumption and were more likely to be heavy coffee consumers.

Discussion

The most consistent differences between smokers and nonsmokers and between those in the two smoking categories were with alcohol and coffee consumption—findings which are in agreement with studies in other populations.[10] In general, smoking status was negatively associated with BMI, a finding also consistent with previous research.[14] Blood pressure was generally lower in smokers than in nonsmokers, although this association was significant only for middle-aged smoking men and women. More consistent associations between smoking status as well as the presence of a dose-response relationship have been reported in other studies.[12]

No significant differences were found for cholesterol levels across smoking groups. The average reported difference in cholesterol levels in smokers and nonsmokers in other studies is approximately 3 percent.[11] In the present analysis, this difference was exceeded only in comparisons of those consuming 10 or more cigarettes per day with those smoking less than this amount in middle-aged women and young men.

Findings relating to physical and emotional health were equivocal, varying by age group and gender. There was limited support that health was poorer in younger, but not older males. In prospective analyses, Hirdes, *et al.*[18] found that smoking status was associated with future risk of disability although this association failed to reach statistical significance. Lack of a strong relationship between morbidity and cigarette consumption in this and other studies may reflect selective survival with the heaviest most vulnerable smokers dropping out of the cohort due to premature mortality.[17]

Our findings have implications for epidemiologic investigations of smoking. Associations between smoking and other health behaviors reinforce the need to control for the effect of these behaviors when examining the impact of smoking on health. Psychological status may also be important to control for in such epidemiologic investigations. Depression, found to be associated with smoking status among women in this study and in previous research,[31,32] is also a risk factor for mortality[33]—particularly among cigarette smokers.[34] Researchers may consider controlling for depression in investigations of smoking and health outcomes as well as exploring possible interactions between smoking and depression.[34,35]

Limitations of this study include potential nonresponse bias and reliance on self-report measures of cigarette consumption. Eighty-seven percent of Mexican Americans approached to participate in the HHANES completed the household interview while 76 percent completed the physician's examination.[36] It should be noted, however, that the weighting procedure incorporated in the present analysis includes adjustment for nonresponse.[36]

Although national estimates of self-reported cigarette consumption are correlated with cigarette sales in the United States (average r = .72),[37] specific analysis of self-report data from the HHANES suggest that underreporting of consumption may have occurred. Based on serum levels of cotinine, a principle metabolite of nicotine, Perez-Stable, *et al*,[38] estimated that 20–25 percent of those reporting 1–9 cigarettes used per day were actually underreporting cigarette consumption, while underreporting estimates for those reporting greater than 10 cigarettes per day ranged from 2–11 percent. These findings suggest that a proportion of subjects in the 1–9 cigarette consumption category in the present analysis may have been misclassified due to underreporting.

In general, this paper confirmed the modest associations found between cigarette smoking and health behaviors and risk factors found in other populations, although these associations did vary by age and gender. Furthermore, few significant associations between smoking and health

JONA Issues Call for Manuscripts

The *Journal of Nursing Administration* (*JONA*), a peer-reviewed journal, is expanding its content to include nursing administration in public, community, and home health care. We are now soliciting manuscripts on issues of concern to public health nurse administrators. Although *JONA* is not a research journal, we encourage data-based articles. For manuscript preparation guidelines, please contact Suzanne Smith Blancett, EdD, RN, Editor-in-Chief, *JONA*/PHN section, 4301 32nd Street West, Suite C-12, Bradenton, FL 34205-2746.

Standardized Comparisons of the Use of Alcohol, Drugs, and Cigarettes Among Military Personnel and Civilians

Robert M. Bray, PhD, Mary Ellen Marsden, PhD, and Michael R. Peterson, DrPH

ABSTRACT

Background: Understanding the effectiveness of policies and programs aimed at combating substance abuse in the military requires comparison with the civilian population from which military personnel are drawn.

Methods: Standardized comparisons of the use of alcohol, drugs, and cigarettes among military personnel and civilians were conducted with data from the 1985 Worldwide Survey of Alcohol and Nonmedical Drug Use among Military Personnel and the 1985 National Household Survey on Drug Abuse. The two data sets were equated for age and geographic location of respondents, and civilian substance use rates were standardized to reflect the sociodemographic distribution of the military.

Results: Military personnel were significantly less likely than civilians to use drugs, but were significantly more likely to use alcohol and cigarettes and to engage in heavy use of alcohol and cigarettes. Heavy drinking was especially likely among young military men. Military women were similar to military men in their smoking and drug use patterns.

Conclusions: Findings suggest that military policies and programs have been notably effective in reducing drug use, but that efforts to limit alcohol and cigarette use should be intensified. Military efforts directed against alcohol abuse should be targeted toward younger men, while smoking and drug prevention programs should be directed toward both men and women. (*Am J Public Health.* 1991;81:865–869)

Introduction

Alcohol misuse, nonmedical drug use, and cigarette use can have negative effects on the health, social life, family relationships, and work performance of users. Although these negative effects can occur within all segments of society, they may be especially serious for United States military personnel who have the unique mission to protect and defend the nation. Because military personnel are drawn from the civilian population, other things being equal, the prevalence and level of use of alcohol, drugs, and cigarettes of the two populations are expected to be similar. Certain differences between military and civilian life, however, may create substance use rates that differ. It has been argued that distinctive military conditions such as relocation overseas, separation from family, or a greater perceived acceptance of use may foster higher rates of use among military personnel than civilians.[1,2] Alternatively, military policies or programs directed toward the elimination of abuse, such as the adoption of a policy of zero tolerance toward drug use and the implementation of an extensive urinalysis screening program, may foster rates of use among military personnel that are substantially lower than among civilians.[3]

Direct comparisons of differences in rates of use among military personnel and civilians may not be meaningful because the sociodemographic compositions of the two populations differ. Military personnel are disproportionately young and male, characteristics generally associated with higher levels of use.[4] Unstandardized rates may not therefore provide adequate comparisons of the extent of differences in substance use between military personnel and civilians.

Several standardized comparisons of alcohol and drug use among military personnel and civilians have been conducted. Observed differences in rates of problem drinking between military personnel and civilians ages 21 to 59 in the late 1970s, for example, were found to be largely but not entirely accounted for by differences in the demographic compositions of military and civilian populations.[5,6] The prevalence of use of alcohol and drugs among military personnel and for civilians ages 18 to 25 was quite similar in 1980,[7] but in 1982 the prevalence of alcohol use was higher and the prevalence of marijuana and cocaine use was significantly lower for military than civilian men ages 18 to 25.[8]

These comparisons are somewhat limited in that they rest largely on measures of the prevalence of alcohol use that are inadequate to describe the quantity and frequency of use, and comparisons of drug use that are based only on the prevalence of use of specific drugs. Further, some comparisons have been based on civilian data that were collected at a different time than the military data,[7] and other studies compared populations that differed in important ways. Some studies, for example, considered both males and females while others considered only males; some considered only ages 18 to 25 while others con-

Military data source: 1985 Worldwide Survey.

sidered a broader age range. No recent military/civilian comparisons of alcohol and drug use are available, and no standardized comparisons of cigarette use have been conducted. For these reasons, general conclusions about military/civilian differences cannot be drawn.

This paper reports results of standardized comparisons of alcohol, drug, and cigarette use among military personnel and civilians in 1985, the most recent date for which comparable data were available. Unlike earlier studies, findings are reported for a broad age range as well as for males and females.

Methods

Data Sources and Analysis Files

Data for military personnel were drawn from the 1985 Worldwide Survey of Alcohol and Nonmedical Drug Use among Military Personnel, sponsored by the US Department of Defense (DoD) and conducted by Research Triangle Institute.* Data on civilians were drawn from the 1985 National Household Survey on Drug Abuse (NHSDA), sponsored by the National Institute on Drug Abuse and conducted by the Institute for Survey Research at Temple University and the Department of Sociology at the University of Kentucky.[9] The two surveys differ in overall questionnaire content, order of item presentation, and field procedures. The 1985 Worldwide Survey, for example, was based on self-report questionnaires administered in group settings, while the 1985 NHSDA data were collected in face-to-face interviews. These differences suggest some caution in making comparisons between the two surveys, but both surveys were carefully conducted and are based on large probability samples.

The eligible population for the 1985 Worldwide Survey consisted of all US active-duty military personnel stationed across the world except recruits, service academy students, persons absent without leave, and persons who had a permanent change of station at the time of data collection. A probability sample was selected for the survey using a deeply stratified, two-phase design. Completed questionnaires were obtained from 17,328 active-duty military personnel for a response rate of 80 percent. Of the responses, 85 percent were obtained in group administrations of the survey at military installations; the remainder were obtained by mailing questionnaires to a subsample of nonrespondents from the group administrations. Estimates of the sociodemographic characteristics of the respondent population showed a close correspondence to sociodemographic characteristics of the actual DoD population values.

The target population for the 1985 NHSDA civilian survey consisted of the household population of the continental United States, ages 12 and older. The household population was sampled using a multistage area probability design with 100 primary sampling units. Individuals in group quarters (military installations, correctional institutions, college dormitories, and hospitals) and those who had no permanent residence (homeless people and residents of single rooms in hotels) were not included in the study. The survey was administered face-to-face, and 8,038 completed interviews were obtained for a response rate of 83 percent.

Before analyzing the data, adjustments to the two data sets were made for differences in residential location and age to ensure greater comparability. To equate for location, military data were limited to respondents residing in the continental United States. Active-duty military personnel living off base in civilian housing were excluded from the NHSDA. To equate for age, both data sets were limited to respondents who were ages 18 to 55 (99.8 percent of the military respondents were in this age range). The adjusted data file for military personnel consisted of 8,084 cases, and the adjusted data file for civilians was 4,894 cases.

Standardization Procedures

As shown in Table 1, the military population is younger, somewhat better educated, and more likely to be male or Black than the civilian population.

Direct standardization[10] was used for comparisons of military personnel and civilians. Civilian data were standardized to the joint distribution in the military of age (18 to 21, 22 to 25, 26 to 34, 35 to 55), race/ethnicity (White, Black, other), education (high school diplomas or less, more than high school), and sex. The standardized estimate for the civilian population is interpreted as the mean that would have been obtained if the civilian population had the same sociodemographic distribution as the military.

Both the Worldwide Survey and the NHSDA used complex, nested sampling designs. The estimates and the standard errors of the standardized civilian data and the military data were computed using

---

*Survey methodology and survey findings for the 1985 Worldwide Survey are described in detail in Bray RM, Marsden ME, Guess LL, Wheeless SC, Pate DK, Dunteman GH, Iannacchione VG: 19[illegible]wide survey of alcohol and nonmedical drug use among military personnel. Report prepared for the Assistant Secretary of Defense (Health Affairs), by Research Triangle Institute, Research Triangle Park, NC, 1986.

Military data source: 1985 Worldwide Survey.

RATIO2, the software package developed by Research Triangle Institute to analyze surveys with complex sampling designs.** T-tests were used to assess the significance of the differences between the standardized rate for the civilian population and the unstandardized rate for the military. Some of the substantial differences between military personnel and civilians have p values greater than 0.05 because of the relatively large standard errors.

Comparisons are reported for males, females, and both sexes combined and for those ages 18 to 25, 26 to 55, and the total group ages 18 to 55. Comparisons for the younger age group provide information about substance use among those at highest risk for use. For the military, this younger group consists largely of enlisted military personnel. The older age group is generally at lower risk, and in the military this group includes a higher proportion of officers.

Measures of Substance Use

The measures of alcohol use are the prevalence of any drinking and heavy drinking during the past 30 days. Any drinking refers to having had one or more drinks of beer, wine, or liquor during the past 30 days. Heavy drinking refers to consuming five or more drinks per typical drinking occasion at least once a week and is based on a drinking-level classification scheme adapted from Mulford and Miller.[11] The measures of drug use are the prevalence of use in the past 30 days of marijuana/hashish, cocaine, psychotherapeutic drugs (stimulants, sedatives, tranquilizers, analgesics), any drug, and any drug except marijuana. "Any drug" includes marijuana or hashish, inhalants, hallucinogens, cocaine, heroin, and psychotherapeutic drugs. The measures of cigarette smoking are the prevalence of any smoking (one or more cigarettes) and heavy smoking (smoking one or more packs of cigarettes per day) during the past 30 days.

Results

Alcohol Use

Table 2 presents standardized comparisons of the prevalence of any drinking and heavy drinking among military personnel and civilians by age group. Overall, military personnel are substantially more likely than civilians to drink and to drink heavily. This pattern of differences is consistent for males and females and for younger and older age groups, although in some cases differences have p values greater than 0.05. The prevalence of any drinking among all military personnel is about 8 percentage points higher than among all civilians, and the prevalence of heavy drinking among all military personnel is about 10 percentage points higher than that among all civilians.

Military/civilian differences in *any drinking* are more pronounced among women than among men. The rate for any drinking for women in the military is about 15 percentage points higher than the rate for civilian women; for men, the difference in military and civilian rates is about 7 percentage points. Younger military women are almost as likely as military men to drink and more likely than civilian men to do so.

Military men and women are about twice as likely as civilian men and women to be *heavy drinkers.* About one-third of younger military men drink heavily, a rate that is substantially higher than for any other group.

Drug Use

The prevalence of any drug use is substantially lower among military personnel than among civilians, as shown in Table 3. The rate of any drug use among all military personnel is about one-third that among all civilians, 8.4 percent versus 24.1 percent. Similarly, the rate of any drug use among military men is about one-third that among civilian men, whereas the rate of use among military women is about half that among civilian women. These tendencies for any drug use generally hold for specific drugs. Drug use among military women is about the same as among military men, whereas use among civilian women is substantially lower than among civilian men.

For most measures of drug use, the prevalence of any drug use is highest among civilian men, followed by civilian women, military men, and military women. The data in Table 3 also show

[a] Stimulants, sedatives, tranquilizers, and analgesics.

[b] Nonmedical use one or more times of marijuana or hashish, inhalants, hallucinogens, cocaine, heroin, or psychotherapeutics.

[c] Nonmedical use one or more times of drugs listed in footnote b except for marijuana or hashish.

Civilian data source: 1985 National Household Survey on Drug Abuse.

Military data source: 1985 Worldwide Survey.

greater drug use among the younger age group than among the older age group (about 10 percentage points for any drug use). This finding holds for both military and civilian populations. Thus, those ages 18 to 25 are at considerably higher risk of drug use than those who are older.

Cigarette Use

Military personnel are in general substantially more likely than civilians to be smokers and heavy smokers, as shown in Table 4. For the total group, the prevalence of smoking is about 5 percentage points higher among military personnel than among civilians, and the prevalence of heavy smoking is about 8 percentage points higher. Differences among military and civilian women are more pronounced than among military and civilian men. The rates of any smoking and heavy smoking among military and civilian men differ by 4 and 7 percentage points, respectively, while the same rates among military and civilian women differ by 13 and 14 percentages points, respectively. Military women are especially likely to smoke and smoke heavily: they have the highest prevalence of smoking (45 percent) and the same rate of heavy smoking as military men (30 percent). Rates of heavy smoking are particularly high among older military men and women, over one-third.

Discussion

After controlling for key sociodemographic characteristics known to be associated with substance abuse, clear differences remain in rates of substance use between military personnel and civilians. Military personnel are, in general, less likely to use drugs than civilians and more likely to drink and drink heavily and to smoke and smoke heavily. A striking finding is the extremely high rate of heavy drinking among younger military men (about one-third).

The substance use patterns of men and women are also of note. Among civilians, women are less likely than men to use drugs, alcohol, or cigarettes. Among military personnel, women are also less likely to use alcohol than men; in contrast, military women are equally as likely as military men to smoke and use drugs.

The precise factors accounting for differences in substance use are unknown but may plausibly be associated with distinctive conditions in military life and in military policies and programs directed toward substance use. The military policy of zero tolerance for drug use, which began in 1981 and is supported by urinalysis testing, has been a significant deterrent. Applicants to military service are tested for drug use, and active-duty personnel identified as users are subject to discharge from the military. This policy has, no doubt, been associated with rapid declines in drug use among military personnel during the 1980s, declines that have been much more rapid than those among civilians.

Further support for the deterrent effect of urinalysis testing comes from a recent study of military applicants.[12] Data from urine tests assessing the prevalence of marijuana and cocaine use found that applicants who knew they would be tested for drug use were less likely to test positive than those who did not know. These results suggest that some drug users who know about the screening program make sure they are "clean" before the test and that others decide not to apply. The decision of some drug users not to apply for military service probably accounts for some of the difference in military and civilian drug use.

TABLE 4—Standardized Comparisons of Cigarette Use in Past 30 Days Among Military Personnel and Civilians, by Age Group

	Age Group/Population					
	18–25 years		26–55 years		Total	
Group/Measure	Civilian	Military	Civilian	Military	Civilian	Military

Civilian data source: 1985 National Household Survey on Drug Abuse.
Military data source: 1985 Worldwide Survey.

The higher rates of drug use among civilians suggest that military policies and practices effectively deter drug use in the military. In contrast, the lower rates of alcohol use and cigarette use among civilians than among military personnel suggest that certain aspects of military life may foster use and/or that military policies and programs directed toward alcohol and cigarette use have not been effective. Concerted efforts to decrease alcohol and cigarette use have been more recent and perhaps less intense than the efforts against drug abuse. The findings suggest the need for the military to intensify efforts to eliminate alcohol abuse and eradicate cigarette smoking. Military programs directed toward alcohol abuse should be targeted primarily toward young men who have the highest rates of heavy use. Programs against smoking should target both men and women.

Recent military policies and programs take a more stringent stance against alcohol abuse and smoking. These include an integrated health promotion program, an antismoking campaign, and specific policies to deglamorize and to limit accessibility to alcohol. This intensification of efforts promises further reductions in substance abuse. Data from the 1988 Worldwide Survey** show progress since 1985, with continuing significant reductions in the unstandardized rates of the prevalence of drug use (8.9 percent to 4.8 percent), alcohol use (86.6 percent to 82.8 percent), and cigarette use (46.2 percent to 40.9 percent) among military personnel in the past 30 days. Standardized comparisons conducted with the 1988 National Household Survey data, which will soon be available for public use, will reveal whether these recent deceases in use by military personnel and related decreases among civilians result in a continuing divergence of rates of use between military personnel and civilians or whether the rates are becoming more similar. Comparisons of the two sets of standardized comparisons will suggest whether the intensified military efforts against alcohol abuse and smoking have been effective. ☐

Risk Factors for Suicide Attempts Among Navajo Adolescents

ABSTRACT

Background: Rates of adolescent suicide in the United States are highest among Native Americans but little is known about risk factors for suicide attempts in this population.

Methods: To identify risk factors for self-reported suicide attempts by Navajo adolescents, we analyzed the 1988 Indian Health Service Adolescent Health Survey that was administered to 7,254 students in grades 6 through 12 on the Navajo reservation. The responses of students reporting a past suicide attempt were compared to others.

Results: Nearly 15 percent (N = 971) reported a previous suicide attempt; over half of those admitted to more than one attempt. Controlling for age, a logistic regression model revealed the following associations with suicide attempts: a history of mental health problems (OR = 3.2); alienation from family and community (OR = 3.2); having a friend who attempted suicide (OR = 2.8); weekly consumption of hard liquor (OR = 2.7); a family history of a suicide or attempt (OR = 2.3); poor self-perception of health (OR = 2.2); a history of physical abuse (OR = 1.9); female gender (OR = 1.7); and sexual abuse (OR = 1.5).

Conclusions: Efforts to prevent adolescent suicide attempts in this population should target individuals with those risk factors of the highest risk and prevalence of exposure. (*Am J Public Health*. 1991;81:870–874)

Introduction

In 1987, over 2,100 youths under age 19 in the United States killed themselves, making suicide the third most common cause of death in the US adolescent population. Although suicide rates in the US population have been relatively stable, rates among youths have tripled over the past 30 years, from 4.5 per 100,000 in 1950 in 13.1 per 100,000 in 1986.[1] Among US ethnic groups, American Indians and Alaskan Natives have the highest rates.[2,3] The suicide rate among Native American adolescents in 1987 was 26.8 per 100,000, more than double the national rate for adolescents of all races.[4]

For every completed suicide, it is estimated that eight or more are attempted.[5] The 1987 National Adolescent Student Health Survey reported that 11.1 percent of males and 17.5 percent of females from a national random sample of eighth and tenth grade students had harmed themselves in a way that might have caused their death.[6] The prevalence of suicide attempts among Native Americans may even be higher. Among a cohort of American Indian high school students attending a boarding school in the southeast US, 23 percent had attempted suicide during their lifetime.[7]

This high rate of self-destructive behavior among Native American adolescents warrants further investigation and culturally appropriate intervention. The 1988 Navajo Adolescent Health Survey offered an opportunity to examine a set of traditional risk factors that are thought to be important in the general population. This population was chosen because it had the largest and most complete participation in the Indian Health Service Adolescent Health Survey conducted in 1988. The purpose of this study was to identify risk factors for self-reported suicide attempts among adolescent students in the Navajo Indian population.

Methods

Instrument

The source of data was the 1988 Navajo Adolescent Health Survey, a subset of the Indian Health Service Adolescent Health Survey. This 162-item survey was designed as a health promotion tool for use by the Indian Health Service and individual communities to identify and address problems in adolescent health. The original instrument was designed by Adolescent Health Program of the University of Minnesota[8] and adapted for use in Native American populations. After pilot testing, the survey was administered to Native American students throughout the United States. Content of the survey included personal data, information about the home and family, general health, nutrition, substance abuse, social concerns, experiences and attitudes regarding sex, mental health, and injury. The data from the Navajo Reservation represented more than 70 percent of the national sample.

Study Site/Subjects

The Navajo Reservation is the largest Indian nation outside of Alaska with an estimated population of 190,000. Schools on or adjacent to the reservation were encouraged to participate, although each school or individual student could decline. A volunteer sample of 47 schools representing grades six to twelve participated in the survey. All students in participating schools were asked to voluntarily respond to the anonymous survey during class time. There was no attempt to survey students absent on that day. The response rate exceeded 70 percent of enrolled students in virtually all participating schools to yield a usable sample of 7,241 responses, representing approximately one-third of all eligible students on the Navajo reservation.

Risk Factors

To determine risk factors for self-report of attempted suicide, we analyzed this survey using one question as the outcome, or dependent, variable: "Have you ever tried to kill yourself?" The independent variables consisted of 28 survey items in eight categories (Table 1) hypothesized to be underlying risk factors for suicide attempts. There were one to six survey items in each category. All of the items, except alienation, were measured by a single survey question.

Alienation was assessed using a nine item scale (Table 2) that explores the respondent's connectedness with the family and community. This scale had substantial internal consistency (Cronbach's alpha = 0.85) and construct validity when compared to other items of a similar nature in the survey.

Students reporting a suicide attempt were compared to those with no such report for each of the hypothesized risk factors. Chi-square statistics were used to establish significance in these comparisons and the significance level was adjusted to .0018 by the Bonferroni correction for multiple comparisons. Items that met this level of significance were entered in a multiple regression equation controlled for age and gender. Both forward stepwise and structured regression strategies were employed in this procedure. Using F tests, items that remained significant after adjustment for the other variables were entered into a logistic model. Estimates of adjusted odds ratios for each risk factor were derived from the coefficients of the logistic regression model. Categorical variables were divided into a series of dichotomous dummy variables; odds ratios presented for these variables represent comparison of the high versus low exposures. Data were analyzed with the SPSS-PC (SPSS Inc., Chicago, IL 60611) and EGRET (Statistics and Epidemiology Research Corp., Seattle, WA 98105) statistical packages.

Results

The sample was 51 percent female with a median age of 14.4 years and ninth

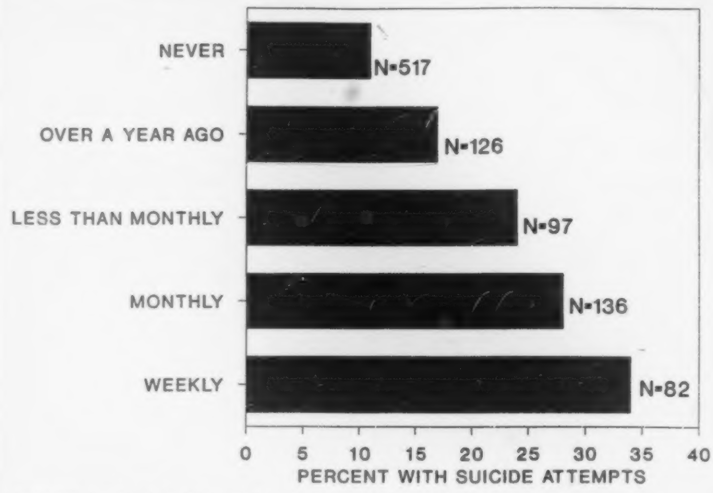

FIGURE 1—Suicide Attempts by Hard Liquor Use among Navajo Adolescents.

grade standing. Exposure to suicidal behavior among friends and family was common in this group of students. About 18 percent of the respondents replied that someone in their family had tried to kill or had killed themselves. Similarly, almost 18 percent had a friend who had attempted suicide and 9 percent had a friend who had completed suicide.

Of all respondents, 6,637 (92 percent) answered the question about suicide attempts; 971 (15 percent) admitted to a past attempt to kill themselves. Thirty-five percent of these attempts had occurred more than one year before the survey and 58 percent of the students had tried to kill themselves more than once. Thirty-six percent of suicide attempts were not reported to anyone and only 15 percent were brought to the attention of a medical professional.

In Table 1, the crude and adjusted odd ratios for hypothesized risk factors that were significant in distinguishing between respondents who had reported a previous suicide attempt, and those who had not, are shown.

In the final model, nine risk factors demonstrated a statistically significant and independent association with a history of suicide attempts. The two strongest associations were a history of a mental, behavioral, or emotional problem requiring professional help (OR = 3.2) and extreme alienation from family and community (OR = 3.2). Exposure to suicide completions and attempts by family and friends also shared strong associations with suicide attempts. Having a friend who previously attempted suicide (OR = 2.8) was more strongly associated with attempts by the respondent than having a family member either attempt or complete suicide (OR = 2.3). The consumption of hard liquor at weekly intervals was also significantly associated (OR = 2.7) with suicide attempts. The frequency of hard liquor consumption was linearly correlated with a lifetime prevalence of suicide attempts (Figure 1). Beer and wine consumption were not significant correlates at any frequency of use after adjustment for hard liquor use.

A self-perception of poor general health was also independently associated with a history of suicide attempts (OR = 2.2). The association of past physical abuse (OR = 1.9) with suicide attempts was marginally stronger than that of sexual abuse (OR = 1.5). Finally, the odds ratio for female gender remained significant after adjustment for covariates (OR = 1.7).

Several risk factors appeared to be associated with a past suicide attempt in the bivariate analysis but were not included in the model because of the many missing values. These variables included both the maternal and paternal consumption patterns of alcohol and the respondent's school performance as measured by the grade point average.

Risk factors which were significant in the bivariate analysis but did not remain significant after adjustment for other covariates, or after correction for multiple comparisons, included: community of residence, history of friend's suicide completion, all of the family structure variables, the weekly use of beer or wine, household density, religiosity of the respondent, the household presence of the natural mother, and an adoptive father or stepfather.

Discussion

To our knowledge, this is the first large controlled study of suicide attempts among Native American adolescents. The lifetime prevalence of self-reported attempts among Navajo students is high, but similar to that reported in the Minnesota and National Adolescent surveys.[6,8] The risk factors ascertained in this study of Native American youth are similar to those described for the general population.

An important finding of this study is the link between the suicide attempts of the respondents and those of their friends and family. Because prevalence of exposure was the highest for these risk factors and because of their strong association with suicide attempts, these risk factors have the greatest public health importance. Although bereavement following a family suicide is recognized to be a risk factor for suicidal behavior in older adults,[9] there have been few controlled studies documenting this risk in children and adolescents. The studies of adolescent suicide clusters, where a number of suicide deaths occur in a community over a short period, have been conflicting as to whether exposure to a friend's suicide is a risk factor.[10–12] But these studies have only evaluated deaths, not attempts, and have studied only suicide deaths associated with a suicide cluster.

Alienation from family and community was independently associated with a history of previous suicide attempt. This supports findings from numerous uncontrolled studies in other populations, including Durkheim's sociologic analysis of suicide.[13]

The association of alcohol and suicide attempts confirms previous findings and demonstrates new ones. Chronic and acute ethanol intoxication appear to play an important role in completed suicides of both White and Native Americans.[14,15] In contrast, there are few data on the role of alcohol in suicide attempts, nor on the differences between varying types of alcohol. After adjustment for beer and wine consumption, use of hard liquor remained the significant alcohol-associated variable related to suicide attempts. The linear relationship between frequency of hard liquor use and the lifetime prevalence of suicide attempts suggests that its consumption (or a close proxy) may play a causal role in suicide attempts.

The finding that past sexual or physical abuse is a risk factor for suicide attempts correlates with reports from other populations. Riggs, *et al*, recently reported similar findings for sexual and physical abuse in a smaller survey of Rhode Island students, although these variables were not adjusted for other behavior and life events.[16] Our study also indicated an interaction between the gender and abuse variables, demonstrating that sexual abuse of males and physical abuse of females are associated with higher risks than the converse situations. This has not been described in other studies.

Mental health problems were expected to be risk factors as their association to suicidal behavior has been well described.[17–19] Despite this, few controlled studies have confirmed this finding in the American Indian population. Manson's survey of Indian adolescent students from a southeastern boarding school demonstrated that those with a past suicide attempt had a higher level of depressive symptomatology.[7] A recent controlled study of adolescents presenting to an urban emergency room for suicide attempts indicated that they were more likely than controls to have a history of mental health care.[20]

There are several limitations to this study. Its cross-sectional design did not allow us to establish the temporal relationship between these risk factors and the suicide attempt. Mental health problems or alienation, may show associations because they may also be sequelae of an attempt. In addition, some associations may represent proxies for other variables not in the model. An example of a potential proxy might be child abuse, where the abuse history is important because it is symbolic of pervasive family dysfunction.

The survey did not measure the severity of the self-inflicted injury. Since only 15 percent of the attempts were reported to medical professionals, we infer that the unreported attempts represented gestures or minor injuries. Alternate interpretations are that potentially lethal attempts were only marginally successful, or that some of these unreported attempts were disguised as unintentional injuries, e.g. single occupant motor vehicle crash.

Because the study was conducted in school, it did not include those students absent on the day of the survey. Students who had been expelled, suspended, or had dropped out before the survey also were not represented. All of these groups may be at higher risk for many of these behaviors and life events. This may have led to an underestimate of the true lifetime prevalence of suicide attempts.

Although the use of anonymous self-reported questionnaires precluded corroboration of responses with existing data sources such as medical and social service records, its anonymity may have been an important safeguard of its validity. Since many of these behaviors are illicit or taboo, adolescents may be reluctant to disclose such information in a survey with identifiers. The validity of the self-reported information is supported by the similarity of these results to those from other studies.

Finally, this survey did not include some potentially important risk factors in this population. Exposure to traumatic deaths other than suicides and adaptability to a bi-cultural environment were not included but may also be important risk factors.[21,22]

The causal model of suicidal behavior is extremely complex and appears to vary between age and cultural groups. The causal model will be constructed using risk factors derived from controlled studies. Future preventive strategies should focus on identified risk factors that can be modified.[23] Furthermore, public health efforts to reduce suicide rates will be most successful if focused on those risk factors with the highest attributable risk. Future research efforts to determine the etiology of suicidal behavior in the American Indian and Alaskan Native populations should be directed toward carefully designed population-based case-control studies. ☐

Job Stress Is "Epidemic," Costly to Business, Study Finds

One in three Americans seriously thought about quitting work in 1990 because of job stress, and one in three expects to "burn out" on the job in the near future.

A recent study also claims that workplace stress is causing far greater turnover, lower productivity, higher absenteeism, and more frequent health problems than was previously recognized. Employees who are overworked or have little control over their job are most likely to be burnout victims.

These are among findings from a study prepared by Northwestern National Life (NWNL) Insurance Company identifying the extent, causes, costs, and solutions related to workplace stress. Unlike many earlier studies, the NWNL research is believed to be the first to correlate causes and cures in all occupations and populations across the United States.

Any major change in the workplace affecting staffing is likely to speed up employee burnout, the research suggests. Significant burnout occurred in companies that had substantially cut employee benefits, changed ownership, required frequent overtime, or reduced the work force.

The findings are from interviews with a representative sample of 600 American workers. To help address the problem, NWNL also assembled a panel of stress and wellness experts to construct a workplace stress test that enables a company to quickly measure its work force stress and identify the consequences and solutions.

Among NWNL's key findings are the following:

- Seven in 10 American workers say that job stress is causing frequent health problems, and is making them less productive.
- Thirty-four percent of Americans thought seriously of quitting their job in 1990 because of workplace stress. Fourteen percent of all employees said workplace stress actually caused them to quit or change jobs in the last 2 years.
- Forty-six percent say their job is highly stressful. This is double the findings of a 1985 National Health Interview Survey that said 20% of Americans experience a high level of stress.
- Seventeen percent report higher absenteeism due to job stress.
- Fifty-three percent of Americans are required to work more than 40 hours a week very or somewhat often.
- Eighty-two percent of workers say victims of burnout deserve disability pay from their employer.
- Peggy Lawless, NWNL's research analyst, noted that job stress and burnout have a foothold in the US work force without regard to region, size of company, type of job, or age of the worker.

Lawless said the survey also shows that companies with supportive work and family policies, health coverage for mental illness and chemical dependency treatment, improved communication, and flexible work hours have almost half the burnout rate of companies that don't have such policies.

Lawless likened workplace stress in the 1990s to the lack of workplace safety in the 1960s. "Stress is less visible than coal dust or dangerous machines, but it's more prevalent and just as damaging to health and productivity."

The research results and the NWNL Workplace Stress Test are contained in a copyrighted report by NWNL called "Employee Burnout: America's Newest Epidemic." Copies can be obtained by calling 612/342-7137.

Patterns of Mental Health Utilization Among Island Puerto Rican Poor

Margarita Alegría, PhD, Rafaela Robles, PhD, Daniel H. Freeman, PhD, Mildred Vera, PhD, Aida L. Jiménez, MA, Carlos Ríos, MPH, and Ruth Ríos, MS

ABSTRACT

Background: This paper describes utilization of mental health services by poor Puerto Ricans living on the island. It examines the utilization rates, within health sectors, and settings for the provision of mental health services.

Methods: Data are based on an islandwide probability sample of 18- to 64-year-old respondents living in low socioeconomic areas. We assessed need with the Psychiatric Symptom and Dysfunction Scales.

Results: Approximately one-third of our study population (31.5%) met criteria for need. Of these, only 32% had received any mental health care in the past year. Need was significantly associated with use of physical or mental health services for mental health problems. We found those who needed services to be five times more likely than those who did not need services to have used one or both sectors of care at least once in the past year. Among the first group 21.8% used the physical health sector to deal with mental health problems in contrast with 17.9% who sought care in the mental health sector. In the physical health sector, subjects used the public and private settings equally. In the mental health sector, 70% of subjects used the public setting.

Conclusions: This suggests the nonpsychiatric physician as a main provider for mental health treatment. (*Am J Public Health*. 1991;81:875–879)

Introduction

We report the distribution of mental health services provided by the medical (physical) and mental health sectors to low income people living in Puerto Rico. The relation of sociodemographic characteristics with utilization of mental health services is examined. Utilization data obtained in this study provide information on the gap between the need for and provision of mental health care.

Researchers have studied the use of mental health and health services by various ethnic minorities.[1–7] Some studies have found underutilization of mental health services by Hispanics,[2–5] while others question this underutilization.[6–7] Discrepant findings have been attributed to treatment surveys versus community surveys, to the criteria used to define Hispanics, and to differences in the need for mental health services.

Previous studies[8–10] indicate that persons of lower socioeconomic status (SES) have a low rate of mental health service utilization. A recurring argument is that the poor hold attitudes and ideologies dissonant with scientific medicine.[11,12] Hoppe and Heller[13] suggest that lower-class populations distrust those outside of their circle of family and friends, having heavy involvement in familial and peer relationships. Differences in values and priorities placed on health across socioeconomic groups may better explain observed differences in the use of mental health and physical health sectors. For example, Ware and Young[14] reported that persons of lower SES value their physical health more than their mental health. Johnston and Ware[15] report that SES appears associated with somatization, recognition of illness symptoms, and behaviors in response to illness. Consistent evidence has shown that a substantial proportion of persons with emotional problems and mental disorders are treated in the physical health sector.[16–20] Hough, *et al*,[21] found that although Mexican Americans made fewer visits to mental health providers than their non-Hispanic counterparts, they did not differ in the proportion of visits to a physical health provider for mental health reasons.

This study concentrates on the population in the lowest socioeconomic strata since there is evidence to suggest this group is greatly exposed to economic strains, physical illness, and disabilities, known risk factors for mental health needs.[22,23] Little is known to explain the use of mental health services for individuals that belong to the lowest income strata.[24] In this paper, we examine the utilization of mental health services by this population on the island of Puerto Rico.

Methods

The target population of this study included the civilian, noninstitutionalized residents, ages 18 to 64, living in low so-

cioeconomic areas of Puerto Rico. The population was sampled using a two-stage stratified cluster sample of the island. The strata were urban and rural, which economically defined sub-strata. The substrata or segments were classified as economically depressed based on an index of media house rent, family income, and house value. These segments were divided into clusters from which 178 were selected for our sample. The list of clusters defined a survey area which contained about 57 percent of the total island population living in poverty. The nonpoor living in these areas were surveyed but excluded from the analyses reported here. The poor people living in nonpoor areas were also excluded from the sample. The sample for this study was obtained using the sampling frame prepared by the Department of Labor and Human Resources, and based on the 1980 Census of Population and Housing as updated by new housing developments in 1986.

The probability sample of clusters yielded 2,682 housing units. Of these, 27.9 percent (748 housing units) were not eligible. Reasons for ineligibility included vacancies (292) and noneligible residents (456) 18 to 64 years of age.

One respondent in each household was randomly selected from among those eligible. The noninterview rate was 8.1 percent distributed as: 2.5 percent refusals; 5.4 percent persons unable to be contacted after three callbacks; and 0.3 percent other breakoff. A total of 1,777 respondents were successfully interviewed during February to October 1989, yielding a completion rate of 91.9 percent. We constructed a poverty indicator based on size of family and number of related children according to the criteria of the Department of Commerce, Bureau of the Census.[25] Of those respondents living in poor areas, 73.6 percent were assessed to be in poverty status according to the 1989 Census definition. Our analyses are limited to this subpopulation.

All analyses incorporate the underlying survey design. Estimation and testing was performed using the program PC Carp.[26] Group differences in sociodemographic characteristics for utilizers of the physical health sector and the mental health sector for mental health services were tested using Z scores without multiple comparison adjustments. Sociodemographic differences with regard to service sectors used were tested with analyses of variance. Differences are not discussed unless the p value was less than 0.05. In all comparisons we will discuss the weighted sample so our inferences will apply to the Puerto Rican poor population residing in low socioeconomic status areas.

Measures

Respondents were interviewed by lay interviewers who gathered data on sociodemographics, psychiatric symptomatology, physical health, and utilization of physical health and mental health services. Questions on utilization of physical and mental health services for treatment of mental health problems were based on those of the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area studies.[20] For the purposes of this paper, health care use will be limited to the formal system of care, recognizing that the informal system of care (e.g. clergy, friends, family) may also be an important link for explaining how Puerto Ricans cope with their emotional problems.

A mental health care visit is defined as a contact with any type of formal health care provider for a mental health problem. Included in the definition are visits to any type of formal health facility, such as a community health center, or to a physical health provider to deal with mental health problems. The mental health related contacts are examined in the physical health sector and the mental health sector. The physical health sector represents visits to a non-psychiatric physician for mental health problems. The mental health sector corresponds to visits to psychiatrists, psychologists, or any mental health treatment program regardless of whether there was a mental health reason for the visit.

Psychiatric symptomatology was assessed by the Psychiatric Symptom and Dysfunction Scales (PSDS). It consists of five subscales: anxiety, depression, psychosocial dysfunction, cognitive impairment, and general psychopathology. The items for these subscales were selected from the psychiatric, epidemiologic, and clinical research literature for the Florida Health Study.[27-30] Psychiatric symptoms and nondiagnosed psychiatric disorder were the criteria employed to determine need for mental health services. The scale provides a normative distribution of psychiatric symptomatology and dysfunctions in the population. They do not diagnose individuals. The PSDS has been found to be a valuable and adequate measure to identify differential levels of mental health need within the general and patient populations, including Hispanics and other ethnic groups on the mainland.[28,29] Persons scoring with moderate or high symptoms on 3 to 5 scales are included in the need category[2] for mental health services and are termed "needers."

These scales were adjusted for number of chronic illnesses, since some PSDS scores increased with the number of chronic illnesses. Specifically, psychosocial dysfunction, anxiety, and depression scores were reduced two, two, and three points, respectively, for every chronic health illness reported by the respondent. Cognitive impairment and general psychopathology scores were reduced by one point for each chronic physical illness. The actual construction of the scale permits no probing to differentiate whether the apparent psychiatric symptom (e.g. sweaty hands) has some physiological origin. Therefore, adjusting the scales in this respect reduces the upward bias due to poor physical health.

Results

The sociodemographic characteristics of respondents who utilized the mental or physical health sectors for mental health reasons are presented in Table 1. In general, utilization of physical health services did not vary with age. Use of mental health services was significantly higher for those 45–54 years old ($p < .05$) compared to those 18–24 and 35–44 years of age. A higher percentage of respondents with less than 10 years of school education than those with higher scholastic achievement reported use of physical health services for mental health reasons during the last year. Use of mental health services was significantly lower among respondents with some college education ($p < .01$) in comparison to those with a lower educational level. The retired or incapacitated were more likely than others to use the mental health sector or both sectors to deal with emotional problems. Sex, marital status, insurance, and zone of residence did not show a statistically significant association with health services sectors used for mental health reasons.

The utilization of the health and mental health care sector for mental health reasons during the previous year is shown in Table 2. As expected, needers are five times as likely to use one or both sectors of care at least once in the past twelve months for mental health problems (31.5 vs 5.8 percent). This discrepancy is even greater when we consider the use of the general health sector at least on one occasion (21.8 vs 3.7 percent) during the last year. These visits were identified by the respondents as health encounters to deal with mental health problems. The utilization of the mental health sector showed a higher prevalence of mental health visits by needers than by non-needers (17.9 vs 2.3 percent). Among users, the intensity varied by sector and need status. Needers averaged 7.3 (±0.9) visits to the physical health providers while non-needers averaged only 3.5 (±0.6) visits ($p < 0.001$). In contrast, there were no significant differences in the mental health sector utilization visits by needers (9.6, ± 1) versus 11.1 ± 2.7 visits by non-needers ($p > 0.25$).

Nearly 13.6 percent of needers of mental health services are receiving care exclusively in the physical health sector (row 4, Table 2). Furthermore, there is a small group of needers who use both sectors for mental health reasons (8.2 percent). This dual usage of mental health services in both the physical and mental health sector rarely occurs among non-needers (0.3 percent).

Table 3 presents the utilization during the last year of the public and private settings for a mental health problem by need status. Utilizers of exclusively the physical health sector were equally likely to choose a private or public setting for mental health care. In contrast, utilizers of exclusively the mental health sector employed by a 3 to 1 margin the public over the private setting. Approximately one-half of the users of public mental health services reported using mental health centers (data not shown).

⁺Does not exclude the use of other sectors.

Discussion

In contrast to other studies,[18,31,32] poor women in our sample were as likely to receive mental health care as men; elevated rates of unemployment (38 percent) among the poor may be a contributing factor to this finding. Unemployment also may be related to diminished social standing and vulnerability to psychological distress in men, leading them to seek mental health services.

Insurance did not appear to facilitate entrance into mental health care. This could be an artifact of Medicaid eligibility, since it was reported by our respondents as noninsurance. Medicaid operates as a centrally administered program by the Department of Health, whereby participants have free access to public health facilities. Public health and mental health services have an open door policy which may render those services accessible to the "uninsured."

Total mental health visits among poor Puerto Ricans (31.5 percent in our study sample) were twice as high as those reported in the ECA sites.[20] Economic factors and impoverished social conditions may contribute to a higher need for mental health services.

The finding that almost 22 percent of the needers went to professionals who are not specialists in mental health suggests a possible link between mental health disorders and physical illness, or difficulties in discriminating psychiatric symptoms from somatic complaints as a cultural expression of discomfort. Findings by

Note: Numbers in parentheses indicate standard errors.
*Private includes both private and combined settings.

Wells, *et al*,[22] suggest that mental health visits to general health providers commonly involve the treatment of both physical and mental health symptoms. An alternative explanation of this phenomenon is that contacts with the general health sector fulfill additional treatment needs, including social support and advice.

Patients' ambiguous definitions of psychiatric symptoms mixed with physical ailments may deter early diagnoses of mental health symptoms by the nonpsychiatric doctor or lead to misdiagnosis. Our study sample may reflect a tendency toward somatization. Economic strains combined with frequent unemployment as well as constant exposure to crime and violence make more flexible community standards of what constitute mental health problems. Such conditions could legitimize feelings of anxiety, depression, or sadness. The social acceptance of psychiatric symptoms may deter family, friends, and health professionals from referring needers to specialized mental health services.

This may be a consequence of the nonpsychiatric physician being gate-keepers of mental health care. Less than one-sixth (15 out of 103) of the specialty contacts were actually referred by physical health providers. Lack of referrals by nonpsychiatric physicians may be a major barrier to access to mental health services. Limited training in recognizing mental health symptoms by nonpsychiatric physicians or a negative attitude toward mental health care may impede referral.

Limitations of this study should be noted. The population surveyed cannot be assumed to be representative of all poor respondents in Puerto Rico or poor Puerto Ricans in the mainland. Poor persons not residing in low income areas of the island, as well as those in institutions (such as prison) or living in the streets, were excluded from this study. These findings cannot be extrapolated to poor Puerto Ricans in the mainland. Regional differences in Medicaid benefit coverage or local availability of services may influence the utilization rates for mental health services. Language barriers may also prevent access to services outside the island.

We cannot confirm self-reported utilization information provided by our respondents, therefore the validity of the information is not measured. It is probable that our measure of need (PSDS) identifies only certain areas of need for mental health services by the poor. We found that the PSDS scales do not detect as needers a high percentage of individuals who fulfill DIS criteria for alcohol abuse and dependence. However, we found a high concordance in the identification of needers by the CES-D, self-perception of mental health, and the PSDS.

Finally, we made empirical adjustments for the upward bias of poor physical health on the PSDS scale scores, although such empirical adjustment could underestimate actual need for mental health services among the poor. In our estimates of need, we sought to identify need for mental health services not due to physical health problems. The reliability of utilization data could be affected by elapsed time between actual use of services and the interview. Data from Kelly, *et al*,[33] suggest that reliability of medical information was not materially affected by the time interval between interviews. However, it was generally better when the time elapsed was less than one year, as was the case in our study.

In summary, the high utilization rate identified in our study group might be related to the organization of the public health care delivery system. The system in Puerto Rico is a vehicle of access to care for all in need, thus the coverage of the population is not constrained by the Medicaid income threshold standards as in the mainland United States. This broader coverage could be instrumental in explaining utilization patterns of Puerto Rico's low income population when compared to their counterparts on the mainland. Such comparisons can help assess the effects of organizational factors that influence or inhibit contact between low socioeconomic groups and mental health professionals. ☐

A Prospective Study of Hospitalization with Gallstone Disease Among Women: Role of Dietary Factors, Fasting Period, and Dieting

Rosely Sichieri, MD, PhD, James E. Everhart, MD, MPH, and Harold Roth, MD

ABSTRACT

Background: Dietary risk factors for the development of gallstones have not been clearly established. We analyzed data from a population-based prospective study to determine dietary risk factors for hospitalization with gallstone disease.

Methods: We evaluated the role of dietary constituents, fasting, and dieting on subsequent hospitalization with gallstone disease among 4,730 women, ages 25 to 74 years, who participated in the first follow-up of the first National Health and Nutrition Examination Survey. Baseline dietary variables were established through a 24-hour dietary recall and a medical history. Proportional hazards models were used to calculate the effects of dietary variables while controlling for baseline risk factors.

Results: After an average of 10 years follow-up, gallstone disease was confirmed by hospital records among 216 women who denied gallstone disease at the baseline examination. The hazard rate of hospitalization with gallstone disease increased with increasing overnight fasting period and with dieting. Intake of fiber showed a small protective effect. The effect of energy intake was significant only among women younger than age 50 years at baseline. Results were not affected by adjustment for known risk factors for gallstone disease or other dietary factors.

Conclusion: A long overnight fasting period, dieting, and low fiber intake may increase the risk of hospitalization with gallstone disease. (*Am J Public Health*. 1991;81:880–884)

Introduction

Cholecystectomy is one of the most common surgical procedures in the United States, ranking fifth among all nonobstetric, therapeutic hospital procedures. In 1987, cholelithiasis, the leading reason for cholecystectomy, was the first listed diagnosis for 522,000 hospital discharges.[1]

Differences in diet are an appealing explanation for the wide variation in the occurrence of gallstones in the United States and internationally.[2,3] Numerous clinical and epidemiological studies have examined potential dietary risk factors for gallstones.[4–14] Such risk factors have included, among others, cholesterol,[4–6] linoleic acid,[5–7] oleic acid,[5–7] total carbohydrates,[6,8] fat,[6,8] fiber,[8–10] calcium,[11] and energy intake.[12,13] However, the results of these studies have not been consistent. Most of the epidemiological studies have used cross-sectional or case-control designs. One prospective study of energy intake found a positive association[12] with gallstones and another found no relation.[13] After examining more than 50 foods and nutrients the only association with diet in a recent prospective study of 88,373 middle age women was a negative one with vegetable fat and protein.[14] Clinical studies have suggested that certain dietary patterns, such as weight loss dieting and prolonged fasting may increase gallstone risk.[15–17]

The first National Health and Nutrition Examination Survey (NHANES I) collected dietary information. Follow-up interviews averaging 10 years later allowed prospective evaluation of dietary factors on subsequent disease. We tested specific hypotheses regarding the roles of dietary constituents, fasting, and dieting on the occurrence of hospitalization with gallstone disease in the longitudinal study of this population.

Methods

Subjects and Study Design

Baseline data, including dietary information, were collected in 1971–75 among a national probability sample of the United States population.[18,19] Follow-up of this cohort occurred in 1982–84 for those ages 25 to 74 years at the baseline examination.[20] The current study is limited to women because of the small number of cases of gallstone disease among men. Analysis was restricted to 4,730 Black and White women after excluding loss to follow-up (1,032 women), self-reported gallstones at baseline (591 women), unavailability of confirmatory hospital records for self-reported diagnosis of gallbladder disease during the follow-up (363 women), and lack of baseline information on gallstone disease (21 women), diet (65 women) or body mass index (two women).

Hospitalization with gallstone disease in the follow-up was coded according to the Ninth Revision of the International Classification of Diseases with Clinical Modification (ICD-9-CM). Cases had hos-

pital discharge diagnoses of cholelithiasis (ICD-9-CM 574) (193 cases) or cholecystitis (ICD-9-CM 575.0–575.1) plus cholecystectomy (ICD-9-CM, procedure 51.22) (23 cases). The first date of hospitalization was regarded as the date of occurrence of clinical gallstone disease. Remaining for analysis were 216 women with hospital confirmed gallstone disease and 4,514 women without evidence of gallstones. A more detailed description of the study cohort and diagnostic criteria has been published.[21]

Variables and Measurements

All independent variables were measured at the baseline examination. Nutrient and energy intake were estimated from a 24-hour recall interview.[18] Participants were asked what they ate and the respective time, by hour and minute, for the 24-hour period beginning at midnight of the day before the interview. Based on these times two variables were created: number of meals and snacks per day, and the duration of overnight fasting period. Total number of intakes at least one hour apart equaled the number of meals and snacks. Overnight fasting period was estimated by the interval between the time of the last meal or snack and the first meal or snack ((24 hours − time of last meal) + time of first meal), using a 24-hour clock. Persons who ate only once during the 24-hour period were assigned a fasting period of 24 hours. Daily nutrient and energy intake were determined using standardized food composition tables applied to the foods reported in the dietary interview.[22] Fiber consumption was based on a provisional table of dietary fiber composition of foods.[23]

Self-reported alcohol consumption, recreational and nonrecreational physical activity, and dieting were ascertained from the baseline medical history interview. Dieting was based on the question "Are you on a special diet?"

Data Analysis

Dietary variables analyzed were those shown in Table 1 plus dieting. All of these variables have been postulated as having potential gallstone promoting activity.[4–13] Overnight fasting period was analyzed both as a continuous variable and as indicator variables (less than eight hour, eight to less than 10 hours, 10 to less than 12 hours, 12 to less than 14 hours, and at least 14 hours) to determine if there was a particularly increased risk with long fasting as has been suggested from clinical studies.[24]

TABLE 1—Medians, 25th and 75th Percentiles for Dietary Risk Factors for Women at the Baseline Examination, NHANES I, 1971–75

Factors	25th	Median	75th
Overnight fasting period (hr)	10.0	11.5	13.5
Number of meals (per day)	3.0	4.0	5.0
Energy (kcal)	1062	1412	1814
Carbohydrates (g)	115	160	210
Fat (g)	39	56	77
Saturated fat (g)	13	19	28
Oleic acid (g)	14	21	30
Linoleic acid (g)	3.0	5.4	8.9
Cholesterol (mg)	135	243	423
Calcium (mg)	287	503	790
Fiber (g)	4.8	7.5	11.2

In accordance with a previous analysis, non-dietary variables included were age in years and body mass index (weight in kg/height in m^2) as continuous variables, Black or White race, and parity categorized as at least four live births or less than four live births.[21] We also included as covariates alcohol consumption (g/day)[25] as a continuous variable and an index of physical activity. This last variable was constructed by summing the self-reported recreational and nonrecreational activities, each categorized in three levels.

Multivariate analysis used proportional hazards survival models with confirmation of the proportional hazards assumption of relatively constant rate ratios during the follow-up.[26] The effect of each dietary variable on the risk of gallstone disease was evaluated controlling for the non-dietary covariates: age at the baseline examination, body mass index (BMI), parity, race, quadratic terms for age and for BMI (age times age and BMI times BMI), and an interaction term for age and race (age times race). Interaction terms between the dietary variables and age, race, and BMI were examined for each dietary factor and were kept in the model if they improved significantly (p value < 0.05) the likelihood ratio of the model.[27] If an age interaction was present, the analysis was divided between persons less than age 50 and at least 50 years of age to simplify the models. Adjustment for energy consumption was made by including the 24-hour energy intake. For models including all ages, an interaction term of energy intake and age was added.

There were 65 women with no information on dieting and very few women (fewer than 13) with missing values for the other variables. Univariate analyses included all available information and multivariate analysis excluded persons with any missing values.

Results

Eighty-two percent of the women reported that what they ate during the 24-hour recall was the way they usually ate. Medians and the 25th and 75th percentiles are shown for each dietary variable at baseline (Table 1). Fifteen percent of women reported being on a special diet.

Survival analysis showed that overnight fasting, dieting, and fiber consumption were significantly related to gallstone disease (p value ≤ 0.03) when each dietary factor was adjusted for body mass index, body mass index^2, age, age^2, race, race times age, and parity. Number of meals, and total carbohydrate intake were marginally related to gallstone disease ($0.05 <$ p value < 0.10). Age influenced the effects of energy and fat intake (Table 2). Hazard rate ratios and 95 percent confidence intervals unadjusted and adjusted for energy intake are shown in Table 3 for those dietary factors with p values ≤ 0.10 in Table 2. Since the effects of energy intake and fat consumption were dependent on age, these variables were evaluated in separate models for women under and over age 50 years at the baseline examination. Energy adjustment reduced the hazard rate ratio for all variables.

When overnight fasting period was divided into five discrete periods the trend for an increased hazard ratio with increased overnight fasting was similar to the exponential model with overnight fasting as a continuous variable. Risk was greatest for 14 or more hours fasting, intermediate for 8–14 hours, and the least for fasting less than eight hours (Figure 1).

Additional analyses that included the significant dietary predictors of gallstone disease (dieting, overnight fasting period, fiber and energy intake), alcohol intake, and physical activity plus the other non-

TABLE 3—Hazard Ratios (HR)[*] and 95% Confidence Intervals (CI) for Dietary Factors for Hospitalization with Gallstone Disease among Women, NHANES I Epidemiologic Follow-up Study, 1971–84

		Unadjusted for energy intake		Adjusted for energy intake	
	Age	HR	95% CI	HR	95% CI
Energy (kcal)[†]	<50	0.69	0.53, 0.88		
	≥50	1.08	0.85, 1.36		
Overnight fasting period (hr)	all	1.33	1.10, 1.60	1.29	1.09,1.53
Dieting (Yes/No)	all	1.67	1.21, 2.23	1.66	1.21, 2.26
Number of meals/day	all	0.79	0.61, 1.02	0.83	0.64, 1.08
Carbohydrates (g)	all	0.85	0.70, 1.02	0.92	0.74, 1.34
Fat (g)[†]	<50	0.73	0.56, 0.95	1.08	0.62, 1.86
	≥50	1.07	0.88, 1.29	1.04	0.67, 1.60
Linoleic acid (g)	all	0.86	0.73, 1.02	1.10	0.90, 1.33
Fiber (g)	all	0.82	0.69, 0.97	0.85	0.70, 1.02

[*]All variables also adjusted for age, age squared, race, body mass index, body mass index squared, parity, and age × race. Models including all ages were also adjusted for energy × age. Except for diet, which was dichotomous, hazard ratios were obtained from models using continuous variables. Calculations were based on:

$$HR = e^{\text{hazard coefficient} \times (\text{75th–25th percentiles})}$$

[†]Variables with age interaction were analyzed by separate models for age groups: < 50 and ≥ 50 years.

dietary covariates specified in Table 3 did not substantially change any of the results (data not shown). Also, a model using as cases all women who reported hospitalization for gallbladder disease whether or not records were available gave essentially the same results (data not shown).

Discussion

In this prospective study of hospitalization with gallstone disease, a long overnight fasting period and dieting emerged as the two most important dietary risk factors for hospitalization with gallstone disease. Few studies have examined these risk factors. In two small, cross-sectional studies a positive association was found between duration of overnight fasting and gallstones.[11,28] A Danish population-based study of ultrasound diagnosed gallbladder disease found a history of "slimming treatments" associated with gallstones in men but not in women.[29] It was not known in the current study what proportion of women reporting a special diet were losing weight.

Long fasting period and dieting may act through diminished gallbladder motility, changes in the bile composition, or both to increase the risk of gallstones. Diverse conditions such as pregnancy,[30] parenteral nutrition,[31] diabetes,[32] and Chagas Disease[33] decrease gallbladder emptying and are considered risk factors for cholelithiasis. A clinical study of eight patients found that gallbladder contractions were reduced at mealtime during weight reduction, and the effect was more marked during prolonged fasting.[34] In addition, saturation of bile with cholesterol increases with fasting[24,35] and with weight loss.[36]

A recent study suggests that increased meal frequency may have a beneficial effect on health.[37] We did not find a strong relationship of number of meals and hospitalization with gallstone disease, but did find that a prolonged overnight fasting period increased the risk. Although fasting period was not a variable conceived when the original data were collected and edited, it is plausible that the times for meals and snacks reported on the 24-hour recall may represent usual eating times because of the regularity of daily activities for most persons. Longest fasting period based on 24-hour recall was also used in a Swedish study of diabetes,[38] but, as far as we know, it has not been validated, although 82 percent of the NHANES I study cohort considered the 24-hour recall their usual way of eating. Also, the increased risk after more than 14 hours of fasting resembles findings of bile composition studies in which lithogenicity of bile occurred only after a long period of fasting. Williams, *et al*, studied women without gallstones and found that saturation of bile with cholesterol was present in 4.5 percent after nine hours of fasting and in 54.5 percent after 16 hours of fasting.[24]

For the analyses based on the dietary composition, associations of gallstone disease hospitalization were found with low energy consumption among the younger group of women and women with low fiber intake. Other epidemiological studies have found negative,[8] positive,[12] and no relationship[13] between energy intake and gallbladder disease. The study that found a positive relationship was most similar to the current study, being a large, prospective study with extensive dietary data and an almost similar case definition. The negative association for energy intake that we found among younger women could be the result of a bias in the dietary recall or of differential energy expenditure between cases and noncases. Another possibility is

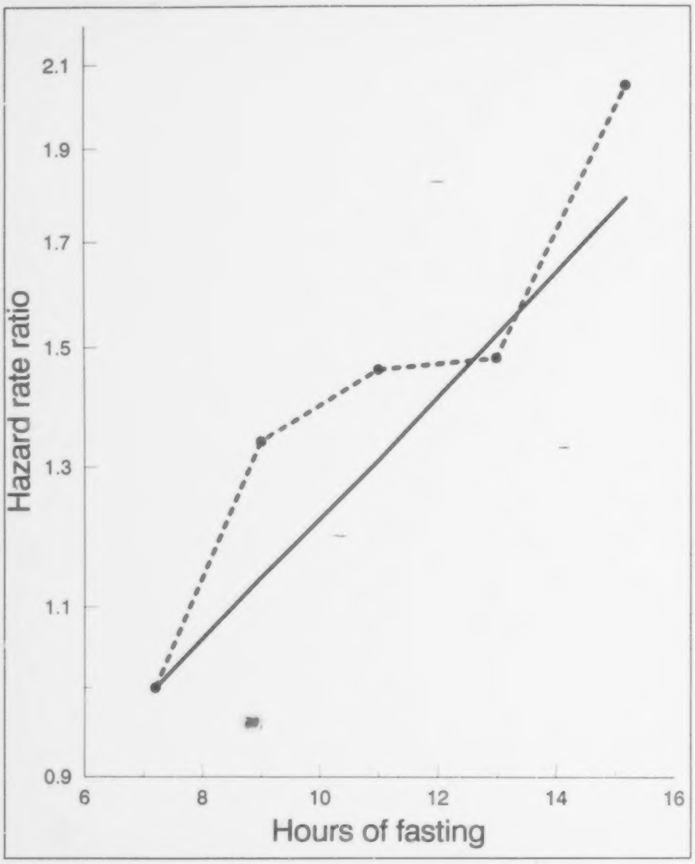

FIGURE 1—Duration of Overnight Fasting Period and Subsequent Hospitalization with Gallstone Disease in Women, NHANES I Epidemiologic Follow-up Study, 1971–84

The solid line represents the hazard rate ratio for overnight fasting period modeled as a continuous variable, compared with fewer than eight hours. Each point on the dashed line is the hazard rate ratio for ranges of overnight fasting period (8–10, 10–12, 12–14, and at least 14 hours) compared with fewer than 8 hours.

that women who have a propensity to form gallstones could have a higher metabolic efficiency and therefore lower energy intake that is independent of BMI.

There are also conflicting reports on the role of dietary fiber in gallstone disease.[9,10] Fiber is a convenient term for heterogeneous groups of poorly digested plant components whose nutritive functions are not well characterized. Colonic metabolism of fiber may affect bile secretion[39] and bind with bile acids in the gastrointestinal tract.[40]

Our results could not be explained by selective exclusion of cases without hospital records because analyses of all reported hospitalization for gallbladder disease, independent of availability of hospital records, showed similar results. Also, the prospective data collection eliminated the possible recall bias that is an unavoidable problem in case-control studies. Biased ascertainment could have occurred in this study if the risk factors analyzed increased the risk of gallstone symptoms rather than increase the risk of gallstones. However, a population-based study using ultrasonography showed that the frequency of dyspeptic symptoms was not different between women with and without gallstones.[41] Misclassification could have occurred in this study through the inclusion of asymptomatic cases of gallstones among the non-case group and the inaccuracies inherent in dietary interview.[42,43] In both cases the influence would be toward a lack of association between the dietary factors studied and gallstone disease.

Our most important findings were the independent roles of fasting and dieting in the development of gallstones. We also found associations with energy intake and dietary fiber. Methodological constraints did not permit absolute rejection of the hypothesis that other nutrients affect gallstone disease hospitalization. □

Cervical Cancer Screening: Who Is Not Screened and Why?

Linda C. Harlan, PhD, Amy B. Bernstein, ScD, and Larry G. Kessler, ScD

ABSTRACT

Background: The decline in death rates from cervical cancer in the United States has been widely attributed to the use of Papanicolaou (Pap) smears for early detection of cervical cancer.

Methods: Pap smear screening rates, beliefs about appropriate screening intervals and factors affecting screening were examined using 1987 National Health Interview Survey data.

Results: Results indicate that through age 69, Blacks are screened at similar or higher rates than Whites. Hispanics, particularly those speaking only or mostly Spanish, are least likely to have received a Pap smear within the last three years. Of women who had never heard of or never had a Pap smear, nearly 80 percent reported contact with a medical practitioner in the past two years, while more than 90 percent reported a contact in the past five years. Overall, the most frequently reported reason for not having a recent Pap smear was procrastinating or not believing it was necessary.

Conclusions: Thus, in developing screening programs, Hispanics, particularly Spanish speakers, must be targeted. In addition, educational programs should target unscreened women who forego the test due to underestimating its importance, procrastination, or because their medical care provider did not suggest the procedure. Women must be intensively educated that Pap smears should be scheduled routinely to detect asymptomatic cervical cancer. **(*Am J Public Health.* 1991;81:885–891)**

Introduction

Although cervical cancer is a readily curable disease if diagnosed and treated early, survival rates have not continued to improve over the mid-1970s and early 1980s.[1] Although these static survival rates may be related to better survivors being diagnosed in the *in situ* stage while women with poorer survival potential are diagnosed later, improved screening and early detection could increase survival rates and lower mortality. In addition, while overall rates of Pap smear screening are reasonably high, a significant number of women are not being screened.

Using the 1973 and 1985 National Health Interview Survey (NHIS), Makuc, *et al*, described changes in use of Pap smears by United States women.[2] They reported that poor women were less likely to use preventive services than nonpoor. They also found that between 1973 and 1985 Black women had substantially increased their use of Pap smears with rates exceeding those of White women. Older women also increased their screening rates, but their rates continued to be lower than younger women.

Using data from a telephone survey, Hayward, *et al*, found, in a multiple regression analysis, age was inversely related to the use of Pap smears.[3] Having health insurance, a higher level of education, being employed, and Black race (compared to Whites and Hispanics combined) were positively related to the use of Pap smears.

In a study conducted by 15 state health departments and the District of Columbia, Parker reported that 72 percent of the female participants had a Pap smear within the last year.[4] Rates decreased with increasing age, were higher in Blacks than in non-Hispanic Whites, and rose with increasing income. In this study, only 1 percent of the women had never had a Pap smear and 0.2 percent had never heard of the test. The knowledge and previous screening rates are much higher than other published rates.[2,3]

In a case-control study of cervical cancer patients, Celentano found that cases were significantly less likely than controls to have ever had a Pap smear or to have had regular Pap smears.[5] Cases were also older at the first Pap smear and more frequently reported not being informed that they should have routine Pap smears.

In England, a general medical practice studied women overdue for Pap smears.[6] Of the 118 women personally contacted, 47 percent said they had no major objection to the test, but it was of low priority. Another 24 percent gave reasons for not having the procedure which were based on incorrect information and 29 percent had strong objections to the test and would probably never consent to having a Pap smear.

Although research suggests Pap smear screening is relatively common, there are subgroups which remain resistant to screening efforts. The literature does not detail the underlying reasons for this failure. The 1987 National Health Interview Survey (NHIS) data offers an opportunity to explore these reasons. This paper will identify subgroups failing to utilize appropriate screening, as well as their underlying rationale.

Methods

Data from the 1987 NHIS were used to examine factors associated with the use of Pap smears by women in the United States. NHIS is a nationwide survey conducted by the National Center for Health Statistics (NCHS). When appropriate statistical methods are applied, estimates are representative of the US noninstitutionalized, civilian population. The 1987 sample design provided for an oversampling of Blacks and the Hispanic population directed at obtaining better estimates for these populations.

In addition to the core questions administered by NCHS, two supplemental questionnaires were added for the National Cancer Institute (NCI). One questionnaire focused on epidemiologic aspects of cancer, such as dietary intake. The second questionnaire addressed issues on cancer control, attitudes, and use of cancer screening. One of the two questionnaires was administered to one randomly selected adult member (aged 18 or over) of each of the approximately 44,000 households; 22,043 individuals completed the Cancer Control Supplement.

The NHIS Cancer Control Supplement included questions about the use of several cancer screening tests. With respect to Pap smears, women were asked, "Have you ever heard of a Pap smear test?" If a woman had not, she was not questioned further. Those women having knowledge of Pap smears were asked if they had ever had a Pap smear and when they last had one. Additional questions were asked about use for health problems, test results, the primary reason for not having the test, method used to advise them of results, and menstrual status, including hysterectomies.

Compliance was defined as having had a Pap smear in the past three years. The NCI's Working Guidelines suggest that after three or more consecutive normal annual Pap smears, the test may be performed less frequently at the discretion of the physician. Three years, often recommended as the appropriate interval, was chosen for the purpose of these analyses.[7]

Reasons for non-compliance were categorized into seven groups: 1) put off (the woman thought the Pap smear was unnecessary; she was simply putting it off or she had no problems and therefore did not have the test); 2) hysterectomy (the woman states she had a hysterectomy and therefore did not have a Pap smear); 3) cost (includes cost and having no insurance); 4) no MD (had no physician); 5) not recommended (the health care provider did not suggest a Pap smear or had said it was unnecessary); 6) embarrassment or fear on the part of the woman, or 7) other or unknown.

Totals, age-specific means and age-adjusted means were calculated using the SESUDAAN procedure.[8] This procedure takes into account the complex multistage sampling of the NHIS study. The RTI-LOGIT program was used for multi-variate logistic regression analysis taking into account the sample design.[9]

Results

The NHIS Cancer Control questionnaire was completed by 12,868 women age 18 and older. The unweighted distribution and weighted (to 1987 U.S. Census estimates) percentage of women by age and race can be found in Table 1. Women, other than non-Hispanic Blacks, non-Hispanic Whites or Hispanics, were excluded from further analyses because of the small sample size (n = 269). In addition, 3.6 percent of the women were unable to recall the date of their last Pap smear. These women were excluded from the analyses.

Age, Race, and Ethnicity

When the proportions of women never having heard of Pap smear are compared by age and race, the results are rather dramatic (Table 2). Many more Hispanic women have never heard of a Pap smear than either Black or White women. The proportion of women under the age of 70 having never heard of a Pap smear was 2.6 percent for White, 5.1 percent for Black, and 19.7 percent for Hispanic women.

As expected, compliance with screening is lower in Hispanics than for either Blacks or Whites (Table 2). Through age 29, compliance rates are similar for Blacks and Whites. From age 30 through 49, however, Blacks are significantly more compliant. In women age 70 and above, compliance rates for White

TABLE 3—Age-Adjusted Percent of Women Never Having Heard of or Interval Since Last Pap Smear by Primary Language Spoken

Language Spoken	Never Heard	Never Had	Last Pap Smear	
			<3 yrs	>3 yrs
Mostly Spanish	34.3 (5.0)	8.7 (2.6)	48.0 (6.5)	8.9 (2.8)
Both Equally	7.3 (3.6)	11.2 (3.7)	60.7 (5.0)	20.8 (4.2)
Mostly English	6.9 (2.7)	8.2 (2.5)	72.4 (3.5)	12.5 (2.9)

TABLE 4—Age-Adjusted Percent of Women Never Having Heard of or Interval Since Last Pap Smears by Poverty Index, Education, and Usual Source of Care

Variable	Never Heard	Never Had	Last Pap Smear	
			<3 yrs	>3 yrs
Poverty Index Ratio				
Below	6.2 (0.8)	10.9 (0.9)	64.8 (1.4)	18.1 (1.0)
At or above	2.5 (0.2)	6.5 (0.4)	75.2 (0.5)	15.9 (0.4)
Education				
<12 years	7.5 (0.6)	9.2 (0.8)	63.9 (1.2)	19.5 (0.8)
12 years	2.4 (0.3)	6.3 (0.5)	74.5 (0.8)	16.8 (0.6)
>12 years	1.5 (0.2)	6.2 (0.5)	79.0 (0.8)	13.3 (0.7)
Usual Source of Care				
HMO	1.1 (0.5)	4.7 (1.1)	85.2 (1.6)	8.9 (1.1)
Doctor's office	2.5 (0.2)	6.9 (0.4)	75.1 (0.6)	15.5 (0.4)
All other sources	4.7 (0.7)	6.5 (0.9)	73.7 (1.3)	15.1 (1.0)
No usual source	7.3 (0.9)	11.6 (1.0)	58.2 (1.4)	23.0 (1.3)
Total	3.3 (0.2)	7.2 (0.3)	73.3 (0.5)	16.1 (0.4)

women increase significantly over those for Black women. Through age 39, Hispanic women are less compliant than either Blacks or Whites. While above this age the rates vary greatly, the much lower rates for Hispanics suggest important differences in screening patterns.

To identify possible explanations for the low Hispanic compliance rate, this group was evaluated according to primary language: 1) only or mostly English (30.1 percent); 2) only or mostly Spanish (34.5 percent); or 3) both languages equally (32.2 percent) (undetermined 3.1 percent, excluded) (Table 3). When age-adjusted means were compared, nearly five times more Spanish speaking women had never heard of Pap smears as compared to English speakers. Much lower compliance rates for Spanish speakers were also apparent.

When compared by birthplace (US, Mexico, Cuba, and Puerto Rico or elsewhere), language appears to be a better predictor of screening compliance (data not shown). Using the self-categorization of Hispanic ethnic origin, Cubans were much less likely to be compliant than Puerto Ricans, Mexicans or "Other" Hispanics, who had similar rates of compliance. However, after adjusting for age, only "Other" Hispanics had significantly lower rates of compliance when compared to Mexicans. This may be important since "Other" Hispanics probably identifies women from South and Central America.

Other Variables

Rates of never having heard of Pap smear are over twice as high for women below the poverty index ratio, a measure of family income adjusted for household size (Table 4). When women above and below the poverty index are compared, it is apparent that the latter are less likely to have had a Pap smear in the past three years.

Education, as well as income, influences health behavior. Women with less than a high school education were three times as likely to have never heard of a Pap smear (Table 4). Women failing to complete high school were much more likely to be non-compliant with screening than those who graduated.

Menopausal status might also affect compliance rates. Women with non-surgical (primarily "natural") menopause were the least likely to be compliant. Premenopausal women were most likely to be screened in the last three years and women with surgical menopause (e.g. hysterectomies) fell between the two groups (data not shown). However, when rates are compared for these three groups after adjusting for age, no important differences in compliance are seen. Women who had undergone hysterectomies were included because excluding them did not appreciably alter other analytic results.

Attitudes toward cancer might influence use of screening Pap smears. When asked whether they could do very little to reduce their chances of getting cancer, women who agreed or strongly agreed were less likely to have had a Pap smear in the last three years than those who disagreed. Those who strongly disagreed were no more likely to have been screened in the last three years than women who disagreed. Women with "no opinion" were much less likely than any other category to have had a recent Pap smear.

For a variety of reasons—such as out-of-pocket expense, attitude of provider or setting where care is given—source of care might influence compliance with screening. Women in health maintenance organizations (HMOs) or other prepaid medical plans were more likely to have been screened within the last three years.* More than one-fourth of the women who reported doctor's office care were non-compliant. This is important since 70 percent of all women reported a physician's office as their primary source of care.

Timing of Pap Smears

Beliefs regarding proper screening intervals would also be expected to alter the frequency. When asked to describe appropriate screening intervals, responses ranged from "never" or "when problems occur" to "more frequently than once per year." Women who were unfamiliar with the procedure were not queried. Of those familiar, 77.9 percent described appropriate intervals as 13 to 36 months (one to three years) while 10.2 percent said annually (data not shown).

Whites were more likely than others to suggest a one- to three-year screening interval. However, Blacks and Hispanics were more likely to suggest a more frequent than annual screening. No important differences were identified among Hispanics when reported timing was examined by language spoken.

Reasons Reported for No Screening

Among those familiar with but non-compliant, the primary reason for not having a Pap smear was examined. The largest category of reasons given by women for being non-compliant was they believed it was unnecessary, had no problems, or had been procrastinating (Table 5). This category accounted for nearly half of the reasons given.

Reasons for not having a Pap smear varied greatly by age. Compared to other age groups, women in the youngest and oldest two groups more frequently stated that the physician had not recommended the test. The two youngest age groups were more likely than others to suggest embarrassment or fear as the reason for non-compliance.

By race no important differences were noted after adjusting for age, except that Whites were more likely than Blacks and Hispanics to suggest that the reason for no current Pap smear was having had a hysterectomy. When the age-adjusted reasons for lack of compliance were compared, surgical postmenopausal women gave "not recommended by the physician" more frequently and "procrastination" less frequently than premenopausal women (Table 5). Cost was a much more important factor for premenopausal women.

Logistic Regression Analyses

To determine factors associated with having heard of a Pap smear or compliance with screening, separate analyses using a backwards, stepwise logistic regression were performed for each as dependent variables (Table 6). Independent variables included: age (continuous), age squared (continuous), marital status (married vs divorced/separated, widow, never married), primary source of care (doctors' office vs HMO, all other sources, and no usual source), place of residence (urban vs rural), education (<12 years vs 12 years, >12 years), self-reported health status, menopausal status, attitude/knowledge about risk reduction (disagree vs strongly agree, agree, strongly disagree, no opinion) and language spoken (English vs Spanish, both languages equally). These variables were selected based on review of literature and/or previous univariate analyses.

In the logistic regression model, age and age squared were important predictors of knowledge of Pap smears, indicating a non-linear relationship of age and knowledge. Women who spoke only or mostly Spanish were less likely to have ever heard of Pap smears than women who spoke only or mostly English. No differences were seen between women whose usual source of care was a physician's office and those with any other usual source of care. However, women with no usual source of care were less likely to have heard of Pap smears than women using doctors' offices for care. Women with less than 12 years of education and those from urban areas were less likely to have ever heard of Pap smears, as were those who strongly agreed, agreed, or had no opinion about the risk statement.

A multiple regression analysis with compliance with screening (no, yes) as the dependent variable was performed (Table 7). These models included all independent variables listed above. Age, although an important predictor of compliance, has an inverted U-shape association with compliance. Compliance appears to peak around age 50, decreasing beyond that age 50 to a point lower than in the youngest age group. Speaking Spanish as the primary language was associated with a lower compliance rate. Never married women were less likely than married women to be compliant. Women who stated their primary source of care as an HMO were more likely to be compliant and women with no source of care were less likely to be compliant than women using a doctor's office. Women with 12 or more years of education were more likely to be compliant.

Discussion

Data here confirm the findings of Makuc, *et al*, that screening in Black women now exceeds screening in Whites.[2] These data also confirm that screening decreases with increasing age and increases with education.[2,3] Although the screening rates are higher for Blacks, the mortality rate is lower for Whites.[1] This may be due to the fact that only recently have screening rates increased above those for Whites. It is also possible that follow-up of positive Pap smears is not as complete for Black women.

Data suggest that Hispanic women are at an increased risk of mortality and morbidity from cervical cancer.* Despite this fact, it is clear that these women are not being adequately screened. Several factors appear to contribute to this lack of screening.

One might suspect that older Hispanic women would be less inclined to learn English and age would therefore confound the relationship between language spoken and compliance. Even after adjusting for age and other variables, women speaking only or mostly Spanish remained less likely to have been screened. Language spoken may be a surrogate measure for acculturation. There may be a cultural avoidance of medical tests such as Pap smears. Although the estimates were somewhat unstable because of small numbers, many more Spanish speakers (17.7 percent) than English speakers (1.5 percent) reported the primary reason for no current Pap smear was because of embarrassment or fear. However, over 11 percent (age-adjusted) of the Spanish speaking women reported they were non-compliant with screening because their physician had not suggested it or had said it was unnecessary. Also contributing may be the fact that few medical care providers are able to fully communicate in Spanish and therefore are unable to convey the importance and need for a Pap smear.

Non-compliant Hispanic women account for approximately 1.6 million unscreened women and Hispanics are the fastest growing segment of our population.[10] Any program to increase screening participation will ultimately need to address existing cultural differences, especially for Spanish speakers.

Usual source of medical care appears also to influence compliance. Women whose usual source of care was an HMO were more likely to be screened than women whose usual source of care was a physician's office. This is an important source of unscreened women since most women still have their primary source of care in a physician's office. Nationwide this would account for about 18.6 million women who were unscreened in the last three years. Some physicians who are the primary source of care for a woman may not provide Pap smear tests, e.g. the internist may think gynecologists should do the test, and a woman may not have regular gynecological care (data not available in this data set). However, screening would probably increase if these physicians provided referrals.

---

*Horm JW: Cancer Incidence, Survival, and Mortality Among Racial and Ethnic Groups in the U.S. (unpublished).

Screening compliance might be affected by the manner in which the results are communicated. Makuc, *et al*, found that the rates for Pap smears in Blacks had increased substantially between 1974 and 1985, suggesting a targeted effort was made in this group.[3] As part of that effort of reinforcing compliance, physicians might be giving test results in person. Indeed, more than half of the Black women received their Pap smear results in this way. Women with less education and lower incomes were more likely to receive the results of their Pap smears in person; however, these women were less likely to have had a Pap smear within the last three years. In addition, women whose usual source of care was an HMO have the highest rate of Pap smear screening, but most commonly these women are not contacted with normal results. Even with diagnostic Pap smears, HMO-enrolled women were still more likely not to be contacted with normal results. These findings suggest that in-person results may instead reflect the provider concern that follow-up might be difficult when results are abnormal, but does not support the hypothesis that in-person results reinforce screening.

Knowledge of proper screening intervals would be expected to influence compliance with screening. When queried about the proper frequency of screening, 75 percent of the women believed the appropriate screening interval was one to three years. However, when examined by race, more Black and Hispanic women believed screening should be performed with a more than annual frequency. Despite the fact that Black women more often reported an inappropriate frequency for Pap smears, they were still more likely to be screened than White women. In addition, while Hispanic women were more likely to say that Pap smears should be performed more than annually, they were the least likely to have received them at the appropriate rate. This suggests components other than knowledge may be encouraging the screening of Black women, since knowledge does not necessarily translate into proper screening practice.

Reasons varied for non-compliance, but nearly 60 percent of the reasons basically revealed a lack of appreciation of the importance of screening. An estimated 12 million US women could be included in this group along with 2.5 million who have never heard of Pap smears. These findings suggest that this population is not adequately educated about the importance of routine screening, lack encouragement from medical providers, or have substantial misunderstanding about the messages from them regarding Pap smears.

Women may be getting mixed messages about screening, with the recommendations for screening frequency seemingly unclear. In addition, the controversy regarding the accuracy of the reading of Pap smears, which has been well reported in the lay press, might convey a message that screening is unimportant or results are of questionable quality.[11] A clear, unambiguous statement about the benefits and timing of Pap smears needs to be emphasized.

Lack of screening compliance can be attributed to multiple causes. Any effective screening intervention must include a multi-dimensional strategy that will successfully address these variables and influence behavior to generate better compliance among women at risk of developing cervical cancer. □

Sustained Effects of an Educational Program to Reduce Sales of Cigarettes to Minors

David G. Altman, PhD, Lolly Rasenick-Douss, Valodi Foster, MPH, and Joe B. Tye, MBA

ABSTRACT

We report 1-year follow-up data from a sample of stores participating in a 6-month community-wide educational effort to reduce cigarette sales to minors in Santa Clara County, California. The proportion of over-the-counter sales to minors at the 1-year follow-up illustrated that although statistically significant reductions were maintained 6 months after the intervention ended, recidivism occurred. Suggestions for achieving long-term reductions in sales to minors are offered. (*Am J Public Health*. 1991;81:891–893)

Introduction

Although there are many factors that influence the decisions that adolescents make to initiate or continue smoking, one that has received only recent attention is access to tobacco. Few smokers begin smoking after their teenage years, and the earlier a young person begins using tobacco, the less likely it is that he or she will be able to quit later.[1] Access to tobacco is conducive to developing and maintaining a tobacco addiction. In field trials around the country, minors' attempts to purchase tobacco from stores and vending machines have been successful more than 50% of the time.[2–10] A survey of 10th graders in two Minnesota communities found a wide diversity of locations from which tobacco had been purchased.[11] In the United States, 947 million packs of cigarettes worth $1.23 billion are sold illegally to minors each year, and the tobacco industry derives 3% of its profits ($221 million) from such sales.[12]

Although most states have laws regulating sales to minors, these laws are rarely enforced.[5,7,13–16] An analysis of 11 active state and local enforcement efforts and 1 200 interviews with health experts, students, parents, and vendors from 18 states found that although 44 states and the District of Columbia have laws prohibiting the sale of tobacco to minors, only 32 violations in 5 states were documented.[13]

Previously, we reported the 6-month effects of a comprehensive merchant and community education program to reduce cigarette sales to minors.[2] One-year follow-up data are reported here.

Methods

In January 1988, 412 diverse stores in Santa Clara County, California that sold cigarettes over the counter and 30 outlets that had cigarette vending machines were visited by minors aged 14 to 16 years. In July 1988, after several months of intervention, which included comprehensive community education, direct merchant education, and contact with chief executive officers of chains and franchises, all stores were revisited by minors. Although the interventions concluded in July 1988, we wanted to assess their sustained effects. The primary data reported here were collected in January 1989, 1 year after the posttest and more than 6 months after the intervention ended. At this follow-up, a random sample of 25% of stores that sold tobacco over the counter, stratified by city (n = 7) and type of store (chain, franchise, independent), was selected and those that were still in business were visited by minors (n = 97). Because a new state law enacted in January 1989 made it illegal for minors to purchase tobacco, we obtained letters from local law enforcement officials allowing teenaged boys and girls to conduct this follow-up without being arrested.

Results

Statistically significant reductions from pretest to follow-up were generally

[a] % change equal to % in pre-test minus % in 1-year follow-up (% rounded).
[b] 95% confidence interval was calculated for change by using sample with data at pretest and 1-year follow-up.
[c] The number of stores for each variable is provided in parentheses.
[d] NS indicates a significance level greater than .10.

obtained even though sales increased between posttest and follow-up. Table 1 presents pretest, 6-month posttest, and 1-year follow-up data. Pretest data are provided for the entire sample of stores and for the sample of stores visited at both pretest and 1-year follow-up. The McNemar nonparametric test for the significance of changes and confidence intervals were calculated on the difference in percent change between pretest and 1-year follow-up for stores with both pretest and 1-year follow-up data.[17]

Discussion

There are discrepancies between what boys and girls are taught in school-based prevention programs and what they observe and experience outside of the classroom. In the classroom, they are told not to smoke, yet in the community, adolescents observe an abundant supply of tobacco, a willingness on the part of merchants to sell them tobacco, a lack of enforcement of laws regulating sales to minors, and very little evidence that society views the problem as a priority. Changing this discrepancy should be a public health priority.

The data reported here illustrate that a comprehensive merchant and community education campaign can achieve sustained effects in reducing sales to minors. However, without continued intervention, monitoring, and we now believe, sanctions, recidivism will occur. Because we wanted to test explicitly the effectiveness of a purely educational intervention, we did not encourage law enforcement to cite stores that sold tobacco to minors. Follow-up data reported here as well as data from other projects that utilized the sanctions of enforcement convince us of the importance of combining education of merchants and the public with the bite of enforcement.[18,19] The experience of the Solano County Cancer Prevention Program in California[19] suggests, that communities will respond more favorably to punitive enforcement efforts if educational interventions are implemented first. Once nonpunitive educational interventions relying on merchants' voluntary compliance are implemented and illegal sales are not reduced entirely, enforcement becomes a more acceptable option. Preceding enforcement with education also allows merchants an opportunity to change their business practices without the immediate threat of punishment.

It is reasonable to hypothesize that if minors have a difficult time obtaining tobacco, then they may be prevented from experimenting with and later becoming addicted to it. Along these lines, studies of school smoking policies have found that making smoking inconvenient may reduce tobacco use by adolescents.[20–22] Without doubt, there will always be some tobacco use by adolescents, just as there is illegal use of marijuana, crack, and other hard drugs. But the more risk young people must take to obtain tobacco and the more societal norms reject tobacco use by young people, the greater the likelihood that young people will not use tobacco. It is also reasonable to ask whether interventions to reduce tobacco sales to adolescents will actually reduce access or simply change where access occurs. Unless sales to adolescents are totally stopped, which is unrealistic in most communities, adolescents who really want tobacco will be able to get it. If, however, community norms and merchant practices about sales to adolescents are applied consistently and comprehensively, we predict that access will truly be reduced. As this study and others have shown, educating the community, merchants who sell tobacco, public policymakers, and law enforcement officials can contribute to reducing the sale of tobacco products to minors.

The 1990s will undoubtedly be a landmark decade for eliminating minors' access to tobacco now that communities around the country have begun addressing the problem. For example, in 1990, research in Minnesota resulted in national attention when dozens of communities throughout the state passed ordinances restricting minors' access to vending machines (Jean Forster, University of Minnesota, personal communication, 1990). The US government also has spoken out on the problem. In May 1990, HHS Secretary Sullivan recommended model state legislation to control minors' access.[14,15] These recommendations dealt with retail licensing, minimum age, graduated penalties for illegal sales, warning signs, enforcement, and vending machines.

Our research suggests that although long-term effects of comprehensive educational programs to reduce tobacco sales to minors can be achieved, interventions must be sustained and rely on multiple intervention strategies. Future intervention research should address minors' access to smokeless tobacco, challenges of intervening in densely populated urban areas, the effectiveness of education combined with enforcement and policy change, the sustainability of intervention effects, and the relationship between reducing tobacco access and youth tobacco use. ☐

Hormone–PMS Relationship More Complex Than Previously Thought

Contrary to popular belief, a new study suggests that premenstrual syndrome (PMS) is not simply related to changes in the levels of reproductive hormones that occur during the premenstrual phase of a woman's cycle. Instead, PMS may be triggered by reproductive hormonal events, as yet unidentified, occurring before the premenstrual phase, or it may be the result of a cyclic mood disorder that is synchronized with (but not caused by) the menstrual cycle.

An estimated 5% of American women are affected by PMS and experience behavioral, emotional, and physical symptoms severe enough to impair their social or occupational functioning. Symptoms include sadness, irritability, anger, tension, loss of energy, and changes in appetite and sleeping patterns.

The study entitled "Lack of Effect of Induced Menses on Symptoms in Women with Premenstrual Syndrome," which appeared in the April 25 issue of the *New England Journal of Medicine*, was conducted by researchers at the National Institute of Mental Health (NIMH) and the National Institute of Child Health and Human Development, in Bethesda, Maryland. NIMH scientists Peter J. Schmidt, MD, and David R. Rubinow, MD, headed the investigation.

The study helps explain why hormone therapy attempting to correct a presumed abnormality during the premenstrual phase is not effective in treating PMS. The findings are consistent with results from previous studies showing the inefficacy of therapy with the hormone progesterone.

"This important study dramatically alters our understanding of and treatment approaches for PMS. It provides valuable new information about the disorder and will stimulate further research to help the millions of women suffering from PMS." said Alan I. Leshner, PhD, NIMH acting director. "Scientifically, the fact that the hormone–PMS relationship is not as simple as previously believed makes PMS a useful model for understanding the very complex relationship between biology and behavior."

What Scientists Funded by the Tobacco Industry Believe About the Hazards of Cigarette Smoking

K. Michael Cummings, PhD, MPH, Russell Sciandra, MA, Amy Gingrass, and Ronald Davis, MD

ABSTRACT

Despite overwhelming evidence documenting the hazards of cigarette smoking, the tobacco industry denies that smoking has been proven to cause disease. The industry professes a desire to clear up the smoking and health "question" and often points to its support of the Council for Tobacco Research (CTR) as evidence of its interest in investigating the health dangers of smoking. This paper presents results of a survey of CTR-funded scientists regarding their beliefs about the health dangers posed by smoking cigarettes. The vast majority of scientists funded by the CTR believe that cigarette smoking is an addiction that causes a wide range of serious, often fatal, diseases. This result suggests that the tobacco industry is unwilling to accept even the opinions of scientists it has deemed worthy of funding. Scientists should consider the ethical implications of accepting funds from the CTR and other tobacco industry-supported institutions. (*Am J Public Health*. 1991;81:894–896)

Introduction

The US Surgeon General has stated that "smoking represents the most extensively documented cause of disease ever investigated in the history of biomedical research."[1] Despite overwhelming scientific evidence against cigarettes, the tobacco industry continues to assert that controversy, debate, and uncertainty exist among scientists concerning smoking as an important cause of illness.[2–4]

In 1972, a confidential memorandum from a Tobacco Institute (TI) vice-president described TI policy as "creating doubt about the health charge without denying it, advocating the public's right to smoke without actually urging them to take up the practice, and encouraging objective scientific research as the only way to resolve the question of the health hazard."[5] Industry spokespersons often point to the industry's support of the Council for Tobacco Research (CTR) as evidence of corporate interest in obtaining scientific evidence on the "alleged" relationship between tobacco use and disease.[3]

The CTR, formed in 1954 by cigarette manufacturers, describes its primary mission as support of research into questions of tobacco use and health.[6] The council awards peer-reviewed research grants to independent scientists who are assured complete scientific freedom in conducting and publishing their studies. Since 1954, the council has provided more than $150 million for 1,108 original studies by more than 700 scientists.[6] In 1989, the CTR listed 204 active projects.

We present results of a survey of CTR-funded investigators, which characterizes what the investigators believe regarding the health effects of tobacco.

Methods and Materials

The study population included the principal investigators of research projects funded by the CTR in 1989.[6] Of 204 investigators listed, 179 were located at universities or institutions in the United States. This survey was restricted to those working in the United States.

Eligible survey participants were mailed a one-page questionnaire assessing their beliefs about the relation between cigarette smoking and various health complications and asking them to rank the importance of 10 different areas of tobacco research. Respondents were asked about their current and past research on tobacco and their cigarette smoking status. A cover letter stated that we were surveying "scientists who had published studies on smoking and health and/or have received research support from organizations interested in the tobacco and health issue."

Of 179 questionnaires mailed to eligible scientists in July 1990, 13 were returned with an incorrect mailing address. A total of 77 completed questionnaires were returned, which represents a response rate of 46% (77/166). No further attempt was made to elicit response. A comparison of responders and nonresponders revealed no significant differences in academic credentials (PhD vs MD), institutional affiliation (university vs other), or the nature of the CTR-funded project (i.e., a tobacco study vs a nontobacco study).

Results

Respondents were asked to "indicate the degree to which you believe the scientific evidence suggests a causal relationship with cigarette smoking" for

eight separate health complications. With the exception of bladder cancer, nearly all respondents rated the relationship between smoking and illness as "strong" or "moderate" (Table 1). Only 1 of 77 respondents was a current smoker. Nationally, approximately 29% of adults smoke.[7]

Only 22% of respondents indicated that any of their current or past research focused on the health effects of tobacco use.

Ninety-four percent of respondents agreed with the statement "smoke from someone else's cigarette is harmful to a nonsmoker"; 91% agreed that most deaths from lung cancer are caused by smoking; and 76 of 77 agreed with the statement "cigarette smoking is addictive" (Table 2).

Rankings of the importance of 10 areas of research on tobacco varied widely (Table 3). Overall, research on preventing tobacco use received the highest ranking, followed by smoking cessation methods.

TABLE 1—Beliefs About the Scientific Evidence Suggesting a Causal Relationship Between Cigarette Smoking and Various Illness Conditions

	Strength of Causal Relationship with Cigarette Smoking:			
Illness/Condition	Strong %	Moderate %	Slight %	Not Established %
Emphysema	88.9	9.7	-	1.4
Chronic bronchitis	77.1	20.0	1.4	1.4
Heart disease	67.1	27.4	2.7	2.7
Low birth weight	51.6	30.6	12.9	4.8
Lung cancer	93.2	5.4	1.4	—
Cancer of the mouth, throat	76.1	19.4	1.5	3.0
Bladder cancer	24.6	56.1	15.8	28.1
Shorter life expectancy	76.4	16.7	4.2	2.8

TABLE 2—Beliefs About the Dangers of Environmental Tobacco Smoke, Smoking as a Primary Cause of Lung Cancer, and Smoking as an Addiction

Statement	Agree Strongly %	Agree Somewhat %	Disagree Somewhat %	Disagree Strongly %
The smoke from someone else's cigarette is harmful to a nonsmoker	52.9	41.4	5.7	—
Most deaths from lung cancer are caused by cigarette smoking	66.2	25.4	8.5	—
Cigarette smoking is addictive	83.3	15.3	1.4	—

TABLE 3—Mean Rankings of the Importance of 10 Areas of Research on Tobacco

Research Area	Mean Rank*	Standard Deviation	Percent Ranking Area as Top Priority
Tobacco use prevention	5.4	2.9	19%
Smoking cessation methods	5.2	2.8	14%
Neoplastic diseases	5.1	3.1	21%
Cardiovascular diseases	5.1	2.4	8%
Pregnancy and infant health	4.9	2.3	7%
Nonneoplastic respiratory diseases	4.6	2.3	—
Passive smoking	4.5	2.7	9%
Chemistry, pharmacology, toxicology	3.5	2.8	6%
Tobacco economics and legislation	3.4	3.4	12%
Tobacco advertising	3.4	2.9	4%

*Ranks range from low = 1 to high = 10.

Discussion

The low response rate is not unusual for a mailed questionnaire survey,[8] but does potentially limit the generalizability of the findings. The comparison of respondent and nonrespondent characteristics does not suggest any systematic response bias. It is possible that among those not responding to the survey were some who feared retribution from the tobacco industry. Such fear, if it existed, would likely be among those whose views are congruent with the majority of the respondents. It is also possible that those with less scientifically acceptable positions or greater commitment to the tobacco industry were less likely to respond, though it would seem to be in the industry's interest to have its views represented in such a survey, if possible. For these reasons, we believe the results accurately represent views of scientists funded by the CTR.

The survey shows that most scientists funded by the CTR believe cigarette smoking is an addiction that causes a wide range of serious, often fatal, diseases. This finding conflicts with the tobacco industry's description of the scientific community as divided on the question and indicates the industry does not accept the opinions even of scientists whose research it funds. Although acknowledging a need for additional investigation of the mechanisms linking smoking and disease, respondents gave the highest priority to research on tobacco use prevention and cessation. None of CTR's active research projects relate to these topics. Despite its stated mission to fund research into the etiology of diseases "alleged" to be related to tobacco use, only 1 in 6 CTR-funded scientists reported conducting research focused on the health effects of tobacco.

We suggest that rather than sponsoring a genuine "program of research into questions of tobacco use and health"[6] the CTR is a public relations vehicle intended to foster a false impression that cigarette manufacturers are interested in investigating the smoking and health "question." We believe such misuse of science raises serious ethical questions for scientists who accept funding through CTR or similar industry-supported entities. Even assuming that adequate funding is not available elsewhere, tobacco industry-supported scientists must ask themselves whether the value of their research in expanding the body of biomedical knowledge outweighs its utility in furthering the corporate interests of a business which kills 434,000 Americans every year.[9] ☐

Gun-Related Deaths Increase Further for Black and White Young Men

The Department of Health and Human Services (HHS) reported today that one out of five deaths of teens and young adults in 1988 was gun related. Among young Black males, close to half of all deaths were firearm related.

Researchers at HHS' National Center for Health Statistics said the firearm-related death rate among Black and White males aged 15 to 24 years had declined in the early 1980s, but then rapidly increased from 1984 to 1988, especially for teenagers and particularly among Black males. Between 1984 and 1988, the firearm death rate among teenagers increased by over 40%, rising 20% from 1987 to 1988 alone, and reaching its highest level to date, 17.7 deaths per 100,000.

"This study shows that for the first time, the firearm death rates for both White and Black male teenagers exceeded the mortality from all natural causes of death," said HHS Secretary Louis W. Sullivan, MD. "For young Black males in particular, the excessive firearm and homicide death rates are appalling and heart-rending.

For Black males aged 15 to 19 years, the firearm death rate and firearm homicide rate more than doubled from 1984 to 1988, with an increase of 38% from 1987 to 1988 alone. By contrast, the nonfirearm homicide rate remained relatively stable. Black male teenagers were almost three times as likely to die from gun-related deaths than from all natural causes of death. For White males 15 to 19 years, the firearm death rate in 1988 for the first time exceeded that of natural causes, by 11%.

HHS Assistant Secretary for Health James O. Mason, MD, who heads the US Public Health Service, said, "The statistics show an American epidemic—without parallel in any other industrialized nation of the world. Physicians and other citizens need to work together to devise the same kinds of educational and prevention techniques that we use to attack other epidemics."

The findings are contained in a study, "Firearm Mortality Among Children, Youth and Young Adults, 1979–1988," produced by NCHS, a part of the Centers for Disease Control. The study examines homicide, suicide, and unintentional firearm deaths among those aged 1 to 34 years.

Does Cigarette Smoking Have an Independent Effect on Coronary Heart Disease Incidence in the Elderly?

Richard Benfante, PhD, MPH, Dwayne Reed, MD, PhD, and John Frank, MD, MSc

ABSTRACT

In order to evaluate the effects of cigarette smoking on coronary heart disease (CHD) in elderly persons in the Honolulu Heart Program, 1,394 men between ages 65 and 74 were followed during an average 12-year period for new cases of nonfatal myocardial infarction and fatal CHD. Incidence rates increased progressively in individuals classified at baseline as never, former, and current smokers, respectively. The absolute excess risk associated with cigarette smoking was nearly twice as high in elderly compared with middle-aged men. (*Am J Public Health.* 1991;81:897–899)

Introduction

While cigarette smoking is well established as a major risk factor for coronary heart disease (CHD) in middle-aged populations,[1–3] the question of whether it is a risk factor for CHD in the elderly has recently arisen because some studies have reported a diminished effect of cigarette smoking on CHD in older persons.[4–9] This reported lack of effect of cigarette smoking on CHD in the elderly is puzzling because the deleterious effects of smoking on CHD risk have been implicated at various stages of atherosclerosis, a pathologic process that generally progresses with age.[9–12] We had an opportunity to examine this question in an elderly group of the Honolulu Heart Program (HHP) cohort. The present analysis was undertaken to determine whether cigarette smoking behavior in the elderly predicts subsequent disease to the same degree as in middle-aged men.

Methods

In the HHP cohort, 1,394 men between ages 65 and 74 and free of clinical cardiovascular disease were followed for 12 years after baseline examination for new cases of definite CHD (non-fatal myocardial infarction and fatal CHD). Details of the differential diagnosis of CHD, surveillance procedures, and case ascertainment in the HHP have been previously described.[13–16]

In order to examine the effect of smoking on CHD risk, age-adjusted incidence rates were calculated by smoking status (current, former, and never) at baseline and expressed in terms of person-years of follow-up. The independent role of cigarette smoking on CHD risk was evaluated using a Cox proportional hazards model that included other major risk factors for CHD.[17,18] Relative risks for cigarette smoking were based on the risk ratio between current smokers and never smokers.

In order to see whether the effect of cigarette smoking on CHD risk was different in elderly compared to middle-aged men, 3,429 of the youngest men in the cohort (ages 51–59 at the examination) were studied as well.

Results

Average values for selected smoking characteristics in elderly and middle-aged men are presented in Table 1. Current elderly smokers on average smoked 20 cigarettes per day compared to 24 cigarettes per day for middle-aged men. Current elderly smokers smoked an average of 10 years longer than middle-aged smokers. For both elderly and middle-aged men, former smokers had higher daily consumption rates than current smokers.

In both age groups there was a consistent and progressive increase in CHD incidence rates by increasing level of smoking experience (Figure 1). Never smokers showed the lowest rates of CHD, followed by former smokers, with current smokers exhibiting the highest. When the relative risks for elderly and middle-aged men were compared in a Cox multivariate lifetable regression that included other major risk factors for CHD (systolic blood pressure, serum cholesterol, diabetes history, body mass index, and alcohol intake) the relative risk for the elderly was 1.62 (95% CI = 1.01, 2.61) compared to 1.80 (95% CI = 1.25, 2.61) for the younger men (Table 2). The difference in relative risks (relative risk ratio) between elderly and middle-aged men was not statistically significant. When an age-smoking interaction term was included in the model, it was also not statistically significant. From the perspective of excess risk

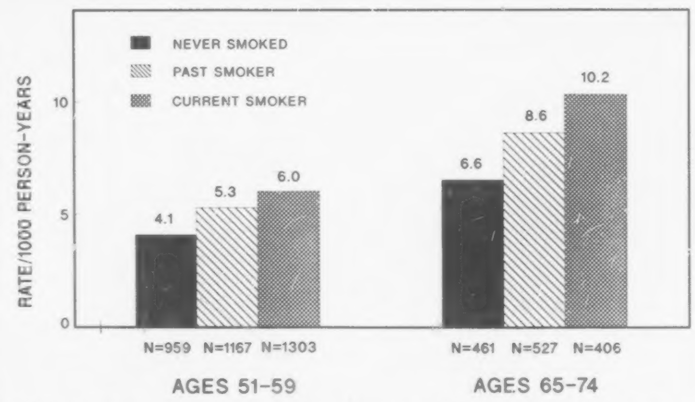

FIGURE 1—CHD Incidence by Smoking Status in Middle-Aged and Elderly Men

for CHD, the difference between current and never smokers for the elderly was 3.6 events per 1,000 person-years, compared to 1.9 events for middle-aged smokers.

Discussion

The results of the present study show that cigarette smoking continues to be an independent predictor of CHD incidence in this cohort of Japanese-American men over age 65, and that the effect is relatively undiminished compared with middle-aged men. CHD incidence for past smokers was intermediate between current and never smokers in both age groups. This is consistent with other evidence that the beneficial effects of quitting are effective later in life as well as during middle years.[1,19-21] It is also important to note that while the relative risk for cigarette smoking on CHD was similar in elderly and middle-aged men, there was nearly a two-fold increase in the excess absolute risk in the elderly men. Thus, since CHD rates increase exponentially with age, the public health impact of a risk factor such as smoking may be greater in older persons even though the relative risk is unchanged.

While a few other studies of older persons have reported an association of cigarette smoking with cardiovascular disease,[19-22] some prospective cohort studies report a diminished effect in the elderly.[4-9] Most notable is the Framingham study which has recently reported that the relationship between cigarette smoking and CHD disappears in both men and women over age 65.[7,8] Several factors may account for differences between the results of Framingham and Honolulu. One is the different analytical methods of relating risk factors to CHD. We used a single baseline measure with an average 12 years of follow-up, compared to the use of the most recent measure from a series of biennial examinations in Framingham. If there was a change in risk factor level, the most recent measure would be used; for example, if a smoker quit, he would be coded as a nonsmoker and then followed for subsequent disease.

Another factor is the potential intervention effect of numerous repeat examinations in Framingham versus just a few examinations in Honolulu. Subjects and their physicians could be notified of high risk levels numerous times in Framingham, but only a few times in Honolulu. Thus, behavioral change or medical intervention would be more likely to occur in Framingham.

There is also the selective attrition effects related to the different time periods of the two studies. The first 20 years of the Framingham follow-up were 1948–68, a period when CHD rates were the highest known in the US. The Honolulu study started in 1965 during a period of declining CHD mortality rates.[23,24] It is possible that these secular effects resulted in differences in the proportion of susceptible subjects reaching the elderly group in the two studies. In addition, the sample of men between ages 65–74 in Honolulu was about twice that for the same age group for men in Framingham, providing a distinct advantage in statistical power.

In conclusion, the present study supports the hypothesis that the biological or clinical effects of such a strong risk factor as cigarette smoking in middle age are maintained over time with increased exposure, and that the benefits of quitting accrue regardless of age. It is therefore recommended that the cessation of cigarette smoking be promoted as part of an overall strategy for prevention of CHD at all ages. ☐

Staff Involvement and Special Follow-up Time Increase Physicians' Counseling About Smoking Cessation: A Controlled Trial

Carol Duncan, RD, MPH, Morton J. Stein, MD, and Steven R. Cummings, MD

ABSTRACT

We compared the counseling behaviors of two groups of health maintenance organization physicians: one group received training about smoking cessation counseling; the other group received the same training plus staff support and appointment time specially designated for follow-up of smokers. We interviewed patients after their office visits to measure smoking counseling. The group receiving staff support and designated follow-up time counseled more and made more follow-up appointments about smoking. (*Am J Public Health.* 1991;81:899–901)

Introduction

Only a minority of smokers recall being counseled to quit by physicians[1,2] and internists who do counsel smokers seldom use effective strategies such as setting quit dates and making follow-up appointments.[3,4] We have found that even after intensive training in counseling, physicians discussed smoking with only half of their smoking patients and infrequently made follow-up appointments about smoking cessation.[5,6] To determine whether greater involvement of administrative and office staff, and provision of specified follow-up time, would increase physician counseling, we conducted a controlled trial.

Methods

We studied two physically separate medical stations at a Kaiser-Permanente Medical Center in the San Francisco Bay Area where internists had not been previously trained in smoking cessation and each saw a minimum of 20 patients per week. Four internists at one medical station agreed to receive training with nursing and administrative support (training-plus), while five internists at another station agreed to receive the training (training-only). One training-plus physician subspecialized in pulmonology; one training-only physician subspecialized in endocrinology, and another in infectious disease. One physician in the training-plus group currently smoked. Two physicians in each group were female, and the mean ages of the two groups were similar (36 years for training-plus; 34 years for training-only).

Research staff met with administrators, then with nurses and their supervisors, then with training-plus physicians and nurses to plan the system of administrative supports. Nurses agreed to ask patients if they smoked, to mark the charts of smokers, and to ask smokers to fill out smoking history forms. Physicians decided to use pre-stamped Nicorette prescription pads. The Department of Medicine designated two appointment slots per week per provider for follow-up of smokers. The group adopted a follow-up protocol using a two-part written Quit-date prescription: one copy was given to the patient and one copy was filed by quit date for nurses to use to telephone patients on quit dates.

All providers concurrently attended two one-hour seminars designed to demonstrate and practice counseling about smoking cessation. These seminars have been described in detail.[5] Training for the training-plus group differed in that nurses and their supervisors attended the sessions. Physicians in the control station were encouraged to ask their office staffs to use reminder stickers to identify smokers.

TABLE 2—Comparison of Physician Counseling About Smoking Between Trained Groups

–	Training-only	Training-plus	Difference	(95% C.I.)
(%)				
Smoking discussed	48.9	68.7	19.8	(6.5,33.2)
Physician initiated discussion of smoking	27.1	62.6	35.5	(22.5,48.6)
Physician asked for quit date	15.8	28.3	12.5	(0.8,24.2)
Smoker agreed to date	7.5	18.2	10.7	(1.0,20.4)
Smoker received written reminder of date	2.3	15.2	12.9	(4.5,21.3)

Referred to program	10.5	25.5	15.0	(4.0,26.0)
Received self-help booklet	9.8	34.3	24.6	(13.1,36.1)
Given follow-up appointment about smoking	9.0	18.8	9.8	(−0.4,19.8)

*Smallest sample sizes: 131 for training-only and 96 for training-plus due to missing data.

We defined a smoker as anyone who had smoked a tobacco cigarette during the past seven days. Research staff surveyed patients in the waiting areas, and asked all smokers to participate. This continued until a minimum of 15 smokers were enrolled per physician. Participants answered a questionnaire about their smoking habit, desire to quit and confidence in ability to quit. As soon as possible after the visit, an interviewer telephoned each smoker to determine if the physician or staff had discussed smoking with them and, if so, what steps the physician had recommended. These data were first collected before any meetings with the training-plus group. The week after training was completed data collection began simultaneously from both training-only and training-plus groups' patients.

To monitor use of designated follow-up appointments for smoking we tallied computerized visit records for "smoking" appointments. We also verified with physicians which of their appointments had actually been used for counseling smokers.

Since outcomes were measured by patient report, patients were the unit of analysis. Statistical significance was tested using t-test for continuous and chi-square for categorical data. We also used logistic regression to adjust for differences in outcomes between the groups, for baseline differences in demographic characteristics in patients, their confidence in quitting, occasional smoking status and type of visit. Because these adjustments did not affect results, we present unadjusted differences in the tables.

Results

We enrolled 335 patients; 26 per physician both before and after training in the training-plus group, and 28 per physician in the training-only group. Telephone interviews were completed for 96 percent of patients within 72 hours of their visits. Patients in the three study groups had similar characteristics, but those enrolled during the pre-training period were less confident of being able to quit, were less often making first visits and more often had urgent problems than those enrolled during the post-training period (Table 1). Compared with smokers in the training-plus group, more patients in the training-only group were regular smokers.

Training-plus physicians discussed smoking with their smoking patients more often than training-only physicians, initiated the discussion more often, asked for more quit dates, gave more written reminders and booklets, referred more patients to groups, programs or professional help, prescribed nicotine gum more often, and made more follow-up appointments than training-only physicians (Table 2). Individual physicians in the training-plus group counseled from 52 to 93 percent of patients, while those in the training-only group counseled from 32 to 63 percent of patients. Office staffs of training-plus physicians discussed smoking with 5.2 percent of patient smokers while office staffs of training-only physicians discussed smoking with none.

Comparing their performance from before the program started to after they received training and office support, physicians in the training-plus group counseled more patients (from 38 to 69 percent), initiated the discussion more often (25 to 63 percent), suggested quit dates more often (3 to 28 percent), prescribed nicotine gum more often (4 to 15 percent), referred more patients to programs (11 to 26 percent), gave more booklets (12 to 34 percent), and made more follow-up appointments (10 to 19 percent). All differences were statistically significant ($P < .05$ for all comparisons).

Forty (60 percent) of 68 available smoking appointments were filled, and 23 (34 percent) of designated appointments were actually used for smokers. Only five (22 percent) of these 23 smokers failed to keep their appointments.

Discussion

In this pilot study we found that involvement of staff and administrators in planning and support of smoking cessation counseling enhanced the effect of physician training. Solberg and Kottke have suggested that it is important to enlist office staff in support of smoking cessation efforts in medical practices[7] and the National Cancer Institute has emphasized involvement of staff and administration in smoking cessation in its most recent booklet for health professionals. We found this approach to be quite acceptable to these volunteers, but it is rarely used in practice. For example, we have found that 60 percent of health maintenance organization physicians never have other staff counsel and 68 percent never make follow-up appointments about quitting.[3]

As expected, the official designation of time for follow-up visits substantially increased follow-up of smokers. Not all appointments were used for smokers, but the total number (23) may have been appropriate since physicians were advised to make appointments with smokers who agreed to quit dates, and 69 smokers had so agreed. There is concern that smokers may frequently fail to keep follow-up appointments about cessation, but the proportion of missed appointments by smokers was within the 15–33 percent range reported for all patients in adult medical practices.[8–10]

This was a pilot study. Our small number of physician subjects were volunteers who were not randomized, and telephone interviews were not done blindly. The end point was physician counseling, not smoking cessation. Larger and longer-term randomized trials are needed to determine whether organizational involvement and follow-up appointments increase rates of smoking cessation among patients as well as to identify which components are most effective.

We conclude that systematic staff support and designated follow-up visits for smokers increase smoking cessation efforts of physicians beyond those that result from training alone. Whether these interventions increase cessation rates deserves further study. ☐

Tobacco Consumption Declining Faster in Canada Than in the US

Murray J. Kaiserman, PhD, and Byron Rogers, BA

ABSTRACT

Consumption and prices of tobacco products in Canada and the United States are compared over the period 1981 to 1989. In Canada, consumption has fallen from a higher level and at a faster rate than in the United States (3.52 kg/adult to 2.48 kg/adult vs 3.21 kg/adult to 2.48 kg/adult). With respect to cost, the real tobacco price index in Canada has grown faster than its US counterpart. These results are attributed to higher taxation practices, vigorous legislation, and the leadership role adopted by the Canadian government during the 1980s. (*Am J Public Health*. 1991:81:902–904)

Can a vigorous national policy that includes high taxation and strong legislation towards smoking bring about significant declines in tobacco consumption? In Canada, the answer is yes.

The most recent figures on total tobacco product consumption expressed as kg of tobacco per person aged 15 years and older show that Canada's consumption fell from a level that was higher than that of the United States in 1981 to the same, lower level by 1989 (Table 1). The choice of the age of 15 years reflects the fact that adult smoking patterns are typically established between the ages of 15 and 18 years.[1,2]

In 1981, Canadians aged 15 or older, consumed 3.52 kg of tobacco per capita.[3] Their American cousins, on the other hand, consumed 3.21 kg per capita in 1981, or 8.8% less.[4]

By the end of 1989, Canadians, like Americans, consumed 2.48 kg annually. For the Canadians, this represented a decrease of 22.8% in total weight of tobacco products consumed. By the end of the decade, the Canadian per capita tobacco consumption rate had declined to reach the same level as its United States counterpart (Figure 1).

Over the 9-year period, the slope of the decline in per capita tobacco consumption in Canada has been about 30% steeper than the trend in the United States. Statistical analysis with a multiregression model shows that the difference in decline between Canada and the United States is statistically significant and is probably attributable to policies within the country rather than external influences.

One of the determinants in short-term tobacco demand is the real price of tobacco products, that is, the price adjusted for inflation.[4,5] Graphs of the real tobacco price index and tobacco consumption for both countries show the expected inverse relationship (Figures 2 and 3).

Canada's steeper tobacco price index curve is indicative of that country's greater willingness to tax tobacco, both federally and provincially (Figure 4). In Canada, federal and provincial taxes together account for approximately two thirds of the retail price of a pack of cigarettes. In the United States, federal and state taxes account for approximately 20% of the retail price.[1,4]

In the 1989 Canadian Federal Budget, the finance minister cited health reasons, in addition to fiscal considerations, in justifying a $0.35 (US) increase per pack of 20 in federal cigarette taxes. Provinces impose their own tobacco taxes in addition to the federal tax, thus further raising the real price of tobacco products. In Canada, the average federal and provincial tax rate is now about $2.25 (US) per pack of 20 whereas in the United States the average federal and state tax rate is $0.38 (US) per pack of 20.[4]*

In addition, the 1989 Canadian Federal Budget reduced the tax rate gap between fine-cut tobacco or roll-your-own (RYO) and manufactured cigarettes. Preliminary sales data reported to Statistics Canada indicate that, in the first half of 1990, consumption of RYO tobacco, long the choice of those Canadian smokers who preferred not to quit in response to cigarette price increases, is now also declining. Cigarette rolling tobacco accounts for 14% of the Canadian cigarette market, but only about 1% of the market in the United States.[1,4]

A factor in Canada's relatively recent trend toward higher tobacco tax rates has been the federal government's adoption of a comprehensive approach to discouraging tobacco use by Canadians. Key elements of the National Strategy to Reduce Tobacco Use include a ban on tobacco product advertising, restrictions on promotional activities, prominent new health warning

*On Feb. 26, 1991 the finance minister increased the federal tax by 52 cents per pack of 20. After subsequent provincial budgets, the average tax rate is now about $3.24 per pack of 20 or about 75% of the retail price.

TABLE 1—Real Tobacco Price Indexes and Per Capita Consumption of Tobacco Products Consumed in Canada and the United States Between 1981 and 1989

Year	Real Tobacco Price Index in Canada[5]	Per Capita Consumption in Canada	Real Tobacco Price Index in United States[4]	Per Capita Consumption in United States[4]
1981	100.0	3.52	100.0	3.21
1982	104.1	3.51	104.8	3.17
1983	115.7	3.32	121.4	3.06
1984	123.6	3.19	124.2	2.92
1985	139.5	3.08	127.0	2.91
1986	157.4	2.90	133.1	2.80
1987	163.7	2.78	137.6	2.68

1989	199.3	2.48	155.1	2.48

messages on tobacco product packaging, health promotion and community support activities around smoking prevention and cessation, economic adjustment programs to assist tobacco growers leaving the industry, and bans or restrictions on smoking in workplaces and on common carriers within federal jurisdiction.

Internationally, Canada has taken a leadership role in banning tobacco advertising, increasing the prominence and legibility of health warning labels, and restricting smoking on longer-duration commercial airline flights.[6] Like Canada, the United States has now banned smoking on flights of up to 6 hours duration, and

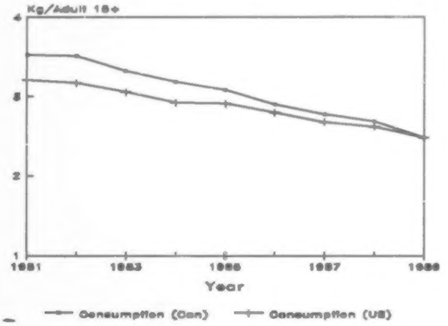

FIGURE 1—Comparison of per capita tobacco consumption in the United States and Canada (1981–1989)

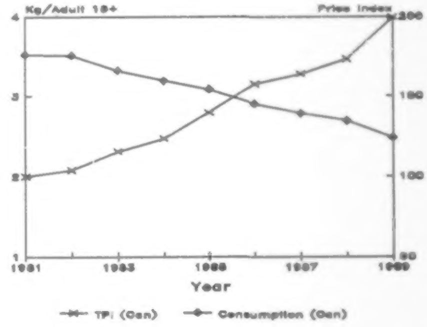

FIGURE 2—Tobacco consumption and tobacco prices in Canada (1981–1989)

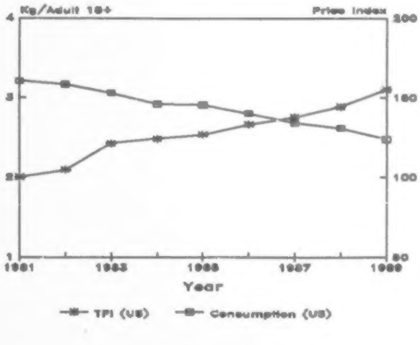

FIGURE 3—Tobacco consumption and tobacco prices in the United States (1981–1989)

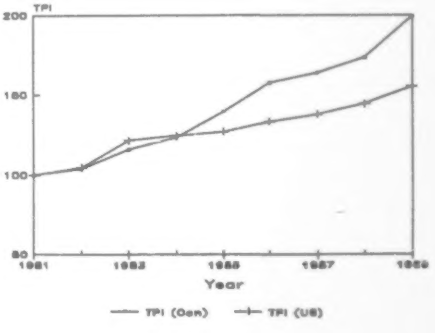

FIGURE 4—Comparison of real tobacco price indices in the United States and Canada (1981–1989)

the US Congress is considering proposals to further restrict or ban cigarette advertising.

For policymakers, the conclusions are simple. Although education and smoking cessation programs can result in moderate declines in tobacco consumption, major declines can be achieved through increased taxation and advertising bans. As a result of an across-the-board strategy to reduce tobacco use, Canada, whose citizens were once characterized as "champion smokers," has caught up with and appears poised to overtake the United States in the trend toward butting out. ☐

The Impact of Time in Treatment on the Employment and Earnings of Drug Abusers

Michael T. French, PhD, Gary A. Zarkin, PhD, Robert L. Hubbard, PhD, and J. Valley Rachal, MA

ABSTRACT

We use data from a longitudinal survey to estimate the effects of time in drug abuse treatment on post-treatment weeks worked and earnings for 2,420 clients in three treatment modalities. The regression analysis shows that time in treatment had a positive and statistically significant impact on these labor market outcomes, but the effects were small for all modalities. Although residential clients experienced the largest relative changes in weeks worked and real earnings, a benefit-cost calculation suggests that additional residential treatment cannot be justified from earnings improvements alone. These results may indicate a need for more employment services while in treatment. (*Am J Public Health.* 1991; 81:904–907)

Introduction

Although recent studies have shown that drug abuse treatment is successful in lowering drug use and criminal activity for some clients,[1–6] little is known about the impact of treatment on clients' employment and earnings.[7] This paper uses multivariate regression models to examine the impact of time in treatment on post-treatment weeks worked and real (inflation-adjusted) earnings of over 2,400 drug abusers.

Methods

We use data from the Treatment Outcome Prospective Study (TOPS), a long-term, large-scale study of 11,000 drug abusers who entered treatment in 1979, 1980, and 1981 at 41 selected drug abuse treatment programs.[4] It provides extensive information about the nature of drug abuse treatment and describes characteristics and behavior of drug abusers prior to treatment, at admission, and at several follow-up intervals. The sample for this study includes all 2,420 clients who participated in the 12-month follow-up interview—the largest follow-up cohort in TOPS. Hubbard and colleagues[4] report and compare sociodemographics at intake and follow-up from a TOPS program for clients in each modality. Rather than repeating those descriptive statistics here, we refer the reader to their book.

We develop regression models to understand the variation in employment and earnings outcomes. For example, consider a simple regression model that describes a labor market outcome as a function of several explanatory variables[8,9]:

$$Y_f = X_f\beta + \gamma PRETOPS + \delta TOPS + \phi POSTTOPS + \varepsilon, \qquad (1)$$

[a] Dependent variable is total real eamings (1983 dollars) from full- or part-time jobs during the 12 months after leaving a TOPS program.

†Significantly different from zero at the 90% confidence level (two-tailed test).

††Significantly different from zero at the 95% confidence level (two-tailed test).

Note: Standard error in parentheses.

where Y_f is a labor market outcome variable at the one-year follow-up, X_f is a vector of explanatory variables at the one-year follow-up, *PRETOPS* is a measure of total time in treatment prior to entering a TOPS program, *TOPS* is total time in a TOPS program, and *POSTTOPS* is total time in treatment during the year after leaving a TOPS program.* From Equation (1) we can estimate the effect of TOPS treatment on a labor market outcome variable, controlling for demographics and prior and ensuing treatment episodes.

Equation (1) may yield biased parameter estimates for the treatment duration variables if unobserved client differences (e.g. motivation, discipline, aggression) are correlated with the time in TOPS treatment.[10] To demonstrate this situation conceptually, consider Equations (2) and (3), which explain labor market variable Y at admission to a TOPS program (Y_a) and one year after leaving a TOPS program (Y_f), respectively:

$$Y_a = X_a\beta + \gamma PRETOPS + v + \varepsilon_a \qquad (2)$$

$$Y_f = X_f\beta + \gamma PRETOPS + \delta TOPS + \phi POSTTOPS + v + \varepsilon_f \qquad (3)$$

where v is an error term. If v includes unobserved client characteristics, single-equation least-squares regressions may yield biased coefficient estimates. To correct this potential problem, we propose a "first-difference" model as illustrated in Equation (4):

$$(Y_f - Y_a) = (X_f - X_a)\beta + \delta TOPS + \phi POSTTOPS + (\varepsilon_f - \varepsilon_a). \qquad (4)$$

By differencing the variables at follow-up with the same variables at admission, we eliminate the error component, v, and all other variables that do not change between admission and follow-up. The treatment duration coefficient, δ, now represents an unbiased estimate of the effect of time in a TOPS treatment program on labor market changes.

Results

Table 1 reports regression estimates for the real earnings specification of Equation (1). Coefficient estimates for the time in TOPS treatment variable were positive for each modality and statistically significant for methadone maintenance and residential clients. On average, one additional week in treatment increased annual real earnings for methadone clients by $21 and for residential clients by $44 during the year following TOPS treatment.

The dependent variable in the Table 2 equations is total weeks worked during the 12 months after leaving a TOPS program. Coefficient estimates for time in a TOPS treatment program were positive and statistically significant for every modality. The coefficients for the residential and outpatient drug free equations imply that six to seven additional weeks in treatment led to one additional week of employment. Methadone clients had a much lower estimated return, with 16 additional weeks in treatment needed for each additional week of employment.

In addition to demographic and treatment duration variables, Tables 1 and 2 report coefficient estimates for program location. Differences in city location coefficients reflect geographical differences in labor markets and program-specific differences in treatment delivery.

Table 3 lists coefficient estimates for the first-difference specifications. Several variables "difference out" because they did not change from admission to follow-up (e.g. race, sex, weeks in treatment prior to TOPS). Focusing on the time in treatment variables, we see that total

weeks in a TOPS treatment program had a positive impact on real earnings and weeks worked in all equations. Only the coefficient estimate from the real earnings specification for methadone clients was not significantly different from zero.

Discussion

This is the first longitudinal study to analyze the impact of length of stay in drug abuse treatment on labor market outcomes. Regression analyses indicate that time in treatment had a statistically significant positive, but small, impact on the follow-up employment and earnings of clients in the major treatment modalities. We believe this result can be explained, in part, by the dearth of training and employment services that were available to treatment clients during this period. Treatment resources were often directed at addiction control and behavior modification at the expense of vocational services. To reverse this trend, greater investments in vocational and employment services may be necessary to produce a strong and lasting effect on labor market outcomes.

Interestingly, time in treatment prior to and following TOPS treatment had a generally negative, but insignificant, effect on real earnings and weeks worked for each modality. This result implies that individuals with more treatment prior to and following TOPS (holding constant time in TOPS treatment) are less likely to have labor market success. Perhaps treatment episodes before and after TOPS signal chronic treatment and employment problems for these clients.

Overall, residential clients experienced the largest impact from time in treatment. From the regression results, we found that residential clients would have earned approximately $44 more if they stayed an additional week in treatment. But the average weekly cost of residential treatment for each TOPS client was approximately $143.[4] Looking only at the earnings outcome of time in treatment, the investment in additional residential treatment would not be cost-beneficial. However, after factoring in the dollar benefits of other treatment outcomes (e.g. lower drug use, reduced criminal activity, improved health status), residential treatment is likely to generate a higher return on the investment. Further analyses of the treatment process, treatment outcomes, and linkages between criminal activity, drug use, and employment are necessary to help design contemporary drug abuse treatment strategies. ☐

Television Viewing and Obesity in Adult Females

Larry A. Tucker, PhD, and Marilyn Bagwell, RN, PhD

ABSTRACT

We measured the relation between time spent watching television per week and obesity in 4,771 adult females. After controlling for age, education, cigarette smoking, length of work week, and weekly duration of exercise, females who reported three to four hours of TV viewing per day showed almost twice the prevalence of obesity (body fat > 30 percent), and those who reported more than four hours of TV watching per day showed more than double the prevalence of obesity, compared to the reference group (<1 hr/day). Part of the TV/obesity association was a function of differences in exercise duration among the four TV viewing categories. (*Am J Public Health.* 1991;81:908–911)

Introduction

Lifestyle plays a key role in the development and prevention of a host of chronic diseases. Until recently, few have recognized television viewing as a significant lifestyle factor. Yet, next to sleep and work, watching TV consumes more time than any other activity in America.[1,2] Adolescents spend more time watching TV each year than they spend in school, and the typical adult averages nearly four hours of TV viewing per day.[1–3]

Research has determined that frequent television viewing may function as a risk factor in a number of disorders.[4–10] Health problems may result from many hours of daily TV watching due to the deceptive and inaccurate health-related messages which are regularly transmitted to viewers.[10,11] However, television's principal problem is probably more related to the physical passivity which accompanies TV viewing rather than the misleading micro-lessons it teaches.

TV has profoundly changed the use of leisure time in America.[2,12] While people watch TV, physical activity tends to be minimal and snacking is prevalent.[10,13,14] Conditions for hypokinetic ailments such as obesity and poor fitness dominate.

In 1986, Tucker[6] studied the connection between television viewing and multiple measures of physical fitness in adolescent males. Findings showed that high levels of TV watching were strongly associated with low scores on tests of fitness, (pullups, situps, sidestep, six-minute run, and pushups). Similarly, Dietz and Gortmaker[5] found that as TV viewing increased, obesity increased systematically in several thousand children aged 6–11 and 12–17. In 1989, Tucker and Friedman[8] showed that time spent watching TV was directly related to obesity levels in adult males. Men who watched more than three hours of TV per day had more than twice the prevalence of obesity compared to those who watched less than one hour per day. To date, the association between TV viewing and obesity in adult females has not been studied; hence, the present investigation was conducted. A secondary purpose was to ascertain the extent to which age, cigarette smoking, hours worked per week, and weekly exercise duration mediate the relation between TV viewing and obesity in women.

Methods

Subjects

Subjects were 4,771 females employed by over 30 different companies in the United States. All subjects worked for companies which paid to have their employees participate in a health promotion/disease prevention screening program offered by Health Advancement Services, Inc. Participants were distributed nearly equally across family income categories ranging from $10,000 to $60,000+. Median age of the sample was 35 years and approximately 83 percent of the females were White, 60 percent were married, 18 percent separated or divorced, and 50 percent reported some college education.

Instrumentation and Procedures

All data were gathered by registered nurses employed by Health Advancement Services as part of their ongoing screening program. Subjects completed an informed consent form and each was tested individually during a private 50-minute examination. A structured, written questionnaire was used to collect the demographic and lifestyle information, including TV viewing, exercise, and smoking habits. A Harpenden skinfold caliper was employed to assess subcutaneous fat at three body sites on each subject: ***thigh***, vertical fold taken on the anterior aspect midway between the hip and the knee; ***triceps***, vertical fold taken on the back of the arm midway between the shoulder and the elbow; ***iliac crest***, diagonal fold taken 2.5 cm above the iliac crest. The sum of the skinfold measurements along with age were used to estimate the total body fat percentage of each subject.[15] Research shows that this three-site skinfold method of

*Females with 30 percent or more body fat were labeled obese.

body fat assessment correlates well with hydrostatic weighing (r = .84).[15] Obesity was defined as 30 percent or more body fat.[16] Body fat, television viewing, and the control variables were categorized as depicted in Table 1. Indirect validation of the body fat,[8,17–20] TV,[4,6–8,19] and exercise duration[17–20] variables has been demonstrated previously.

The relation between duration of TV viewing and body fat was indexed by the Mantel-Haenszel chi-square statistic which shows the extent of the linear association between ordinal-level, categorical variables.[21,22] The relation between TV viewing and obesity was measured by the odds ratio[23] with subjects who reported less than one hour of TV watching per day used as the reference group. Cochran-Mantel-Haenszel summary risk estimates were used to assess the TV/obesity relation with the potential confounders controlled.[24]

Results

Almost 60 percent of the subjects reported watching one to two hours of TV per day, while approximately one in four indicated three–four hours of daily TV viewing (see Table 1). More than four hours of TV viewing per day was reported most often by subjects who were young or old, by the uneducated, by smokers, by non-exercisers, and by those with short work weeks. Obesity, measured in nearly one-third of the adult females, was more common among older subjects, the uneducated, never and ex-smokers, non-exercisers, and those with long work weeks.

Table 2 shows the estimated risk of obesity by TV viewing time without adjustment and with adjustment for the control variables displayed in Table 1. After adjustment for all of the potentially confounding variables, subjects who reported four+ hours of daily TV watching showed more than two times the prevalence of obesity, and subjects who reported three–four hours of daily viewing showed almost twice the prevalence of obesity compared to females who watched less than one hour of TV daily (see Table 2).

Age had the strongest confounding effect on the TV/obesity relation of any single control variable. After adjustment for age only, estimated risk of obesity was increased by an average of 15 percent for the three TV viewing groups compared to the reference group. Control of exercise duration, in addition to the other potentially confounding factors, also affected the TV/obesity association. Specifically, estimated risk of obesity was decreased by approximately 18 percent for the four+ hour/day viewers and 12 percent for the three–four hour/day viewers compared to the reference group.

Discussion

According to the results, adult females who watch four or more hours of TV per day tend to have more than double the prevalence of obesity compared to those who watch less than one hour daily, as in adult males[8] and children.[5] However, because of the correlational nature of this study, cause-and-effect conclusions are not warranted. Although excessive TV viewing may actually contribute to obesity in women, it is plausible that obesity leads to an abundance of TV watching. As with adult males,[8] females who are fat may be

TABLE 2—Estimated Risk of Obesity by Television Viewing Group

*Subjects who were found to have 30 percent or more body fat were labeled obese.

more inclined to watch TV as a primary source of recreation because of the minimal exertion required, whereas non-obese women may prefer other pastimes which demand greater physical involvement.

The strong association between TV watching and obesity in females could be the function of a "third variable" or confounding factor. Each of the control variables of the present study was strongly related to both TV viewing and obesity, except smoking, which was strongly associated with obesity only. Simultaneous adjustment for differences in age, education, length of work week, smoking, and weekly exercise duration substantially increased the estimated risk of obesity for the television watchers, especially the high-duration viewers.

Duration of weekly exercise had a meaningful impact on the TV/obesity relation. High-duration TV viewing was 80 percent more common and obesity was 45 percent more common among non-exercisers compared to those in the highest exercise group (see Table 1). Apparently, part of the reason women who watch a lot of TV tend to be more obese is because they tend to exercise less. If these women spent more time exercising, perhaps in place of some TV viewing time, risk of obesity would likely be decreased.

Other factors not measured in this investigation could confound the TV/obesity association. Diet is a good example. Because television watchers digest thousands of commercial and program messages which encourage consumption of non-nutritious foods,[25–30] and because snacking and eating foods which are advertised on TV are closely linked with television viewing,[10,13,14] it is possible that high-duration TV watchers are more obese than low-duration TV viewers because they consume more food, particularly more junk food, than their counterparts.

Perhaps the most cogent explanation of the association between TV viewing and obesity is based on a dynamic model: as TV viewing time increases, exercise tends to decrease and snacking tends to increase. As exercise decreases and snacking increases, obesity tends to increase. And as obesity increases, attraction to passive recreation, such as watching TV, tends to increase—a cycle of mutual interaction and reinforcement. Future research relative to the TV/obesity relation will need to consider the dietary intake of subjects as well as their physical activity levels. Furthermore, because subjects in this sample were mostly White and well-educated, generalization to other populations will require additional study.

Without question, watching television is a powerful and pervasive lifestyle factor in our society. Given the enormous amounts of time devoted to this idle pastime and the many subtle and distorted health-related messages conveyed by the medium, it is not surprising that children and adults are influenced by TV to a degree far surpassing earlier beliefs.[1–3] Greater effort needs to be directed toward the study of television's influence on health and its role as a precursor of disease. ☐

Characteristics of a Random Sample of Emergency Food Program Users in New York: I. Food Pantries

Katherine L. Clancy, PhD, Jean Bowering, PhD, and Janet Poppendieck, PhD

ABSTRACT

Food pantry users throughout New York State were studied and many demographic differences found between New York City and Upstate New York respondents. Seven percent of households had no income and median income as percent of the poverty level was 59 percent. Slightly more than 40 percent were spending over 60 percent of their incomes on housing. The data from this survey, the first in New York State to employ a random sampling design, demonstrate a sizable gap between household needs and available resources. (*Am J Public Health*. 1991;81:911–914)

Introduction

Food pantries and soup kitchens have become symbols of hunger and poverty in the United States. Food drives are an accepted feature of life and the Emergency Feeding System (EFS), once regarded as a response to a temporary situation, has become institutionalized. As this occurs, government agencies, scholars, hunger activists, and emergency food providers have begun to question the advisability of expanding or even maintaining the system. Many issues are involved in the emerging debate, including the needs of those using the system, which was the focus of our studies.

New York is one of a few states that provides funding for the operation of its EFS which is composed of food pantries, soup kitchens, and food banks. In 1987 there were 414 pantries in New York City (NYC) serving 2.9 million people and 1,143 in upstate New York plus Long Island (Upstate) serving 2.4 million.[1] This and the following report[2] present data from a survey of persons utilizing the food pantry and soup kitchen components of the EFS throughout the state.

Methods

The food pantry survey was conducted from October 1988 to February 1989, at a random sample of sites drawn from the Bureau of Nutrition census.[1] At each site, selection of individual clients was as random as conditions permitted. The final sample included 311 clients from 29 pantries Upstate and 208 clients from 19 sites in NYC.

The interviewers, mainly students in social science and nutrition, were trained at Syracuse University or Hunter College. The 20-minute interview included primarily closed-ended questions about client demographics, sources and amounts of income, and participation in food and other assistance programs.

The census had shown that the numbers of people served per pantry ranged from a few to 128,000 per year. To verify that our random sampling procedure had preserved this diversity, we found no significant difference between the percentages of clients coming from larger or smaller sites in either Upstate ($\chi^2 = 0.547$, df = 1, p > 0.3), or NYC ($\chi^2 = 0.040$, df = 1, p > 0.8).

Results

As shown in Table 1, more of the NYC sample was age 60 or older. Within the older age group, there was no difference between geographic areas in the percentage of persons living alone; however, among respondents ages 36–59, a larger percentage lived alone in NYC than Upstate.

Income sources are presented in Table 2. Approximately 50 percent of the Upstate sample received public assistance, while 36 percent of the NYC households did so. Household income distributions (Table 3) were significantly different due to a larger percentage of households with higher total incomes Upstate. Approximately 40 percent of each sample had incomes less than 50 percent of poverty.

Sixty-two and 52 percent of Upstate and NYC respondents, respectively, were on Medicaid (χ^2 = 5.030, df = 1, p = 0.025). Approximately one-third of each group received a housing subsidy. Despite this, 45 percent of Upstate and 41 percent of NYC households spent more than 60 percent of their incomes on housing (shelter and utilities).

There was a highly significant difference (χ^2 = 18.286, df = 3, p = 0.0001) in length of time that households had utilized food pantries due to both more long-term users (>3 years) Upstate and more short-term users (<6 months) in NYC. Table 4 shows dissimilarities in households' use of other food programs with regard to use of soup kitchens, school meal programs, and senior meals.

Table 5 presents selected demographic characteristics of food stamp users. In both groups, neither living alone or living with others, nor educational level were related to food stamp use. Upstate, significantly more females, more households with children, and fewer seniors were on the program. In NYC, only employment status was significantly different.

The monthly food stamp benefit per household was significantly different ($129 Upstate and $95 NYC) and the Upstate per capita benefit was also significantly higher. Both samples showed significant differences between food stamp users and non-users with regard to income as a percentage of poverty level (Table 6).

Discussion

Since federal poverty income thresholds are based upon the cost of a mini-

mally adequate diet, households below the poverty level are, by definition, at risk of being unable to purchase such a diet.[3] The median income of all participating households was 59% of poverty. Furthermore, federal poverty guidelines were developed when shelter costs were far lower, and the large percentage of income now spent by households further reduces the amount available for food.

Some differences were noted between Upstate and NYC respondents with regard to the extent of use of food programs. People Upstate had utilized pantries for a longer period of time, and there was a positive significant relationship between food stamp participation and length of food pantry use. Food stamp users also made greater use of other food programs. These tendencies suggest that these households are dependent on the EFS even though they are making use of the welfare system in a fairly inclusive manner. In NYC there was not, in most cases, significantly greater use of other programs by food stamp recipients, although the actual percentages of those using soup kitchens, senior meals, etc, was often higher than in the Upstate sample.

Receipt of welfare or food program benefits does not preclude the need for emergency food. Nearly half of respondents were receiving public assistance, but in New York State in 1988 AFDC plus full food stamp benefits brought a household to only 89% of the poverty level.[4] In the Upstate and NYC samples, respectively, 38 percent and 40 percent of respondents 65 and over lived on only Social Security payments which places them near the poverty level.[5] Nearly one-fourth of households included a wage-earner, but a full time minimum wage job brought a household of three to 74 percent of poverty and a household of four to only 57 percent of poverty.[6]

The percentage of households having incomes below 50 percent of the poverty level is similar to the nationwide figure.[7] These households more frequently had children, and, not surprisingly, were less likely to be employed. In both locations, non-White households were significantly more likely to have an income below 50 percent of poverty.

Our findings portray a population in need, and at risk of the health hazards

associated with poor nutrition. In concert with similar data from non-random studies done in New York State between 1985 and 1987,[8–10] and additional analyses of this study,[11] a picture emerges of a sizable gap between household needs and available resources, a gap that food pantries have helped to bridge. If private food assistance diminishes (as has been predicted), government aid to the poor must be expanded or the risk of decreased food security and poor nutrition will increase. ☐

Acknowledgments

This survey was supported by a grant from the New York State Department of Health, Bureau of Nutrition and the New York State Legislature.

We would like to thank Dr. Janice Dodds, Deborah Spicer, and Thomas Melnick, from the New York State Department of Health, for their support and assistance. We are grateful to the study coordinator, Janet Hiemstra, for her invaluable work, and to all the interviewers from Syracuse and New York City. Dr. Susan Borker (Syracuse University) was our statistical consultant and Dr. Diane Murphy (Syracuse University) assisted with the interviewer training. We thank the directors and staff at all participating food pantries throughout the state, and the individuals who agreed to answer our questions.

Characteristics of a Random Sample of Emergency Food Program Users in New York: II. Soup Kitchens

Jean Bowering, PhD, Katherine L. Clancy, PhD, and Janet Poppendieck, PhD

ABSTRACT

A random sample of soup kitchen clients in New York City was studied and specific comparisons made on various parameters including homelessness. Compared with the general population of low income persons, soup kitchen users were overwhelmingly male, disproportionately African-American, and more likely to live alone. The homeless (41 percent of the sample) were less likely to receive food stamps or free food, or to use food pantries. Fewer of them received Medicaid or had health insurance. Forty-seven percent had no income in contrast to 29 percent of the total sample. (*Am J Public Health*. 1991;81:914–917)

Introduction

Soup kitchens, charitable organizations that provide free meals for consumption on the premises, were once regarded as relics of the depression era, useful only to serve the victims of disasters or the disreputable poor in the skid row sections of large cities. Since the early 1980s, however, soup kitchens have again become a significant source of food for the poor.[1]

In New York State, where a recent census identified 189 soup kitchens in New York City (NYC) and 138 in upstate New York and Long Island (Upstate),[2] the State Department of Health provides some funding for soup kitchens through the Supplemental Nutrition Assistance Program[3]; thus the future of the kitchens has become a question for public policy. This report presents data from a survey of persons utilizing soup kitchens in New York City. Upstate kitchens were not surveyed because they had recently been studied.[4]

Methods

The survey of 263 soup kitchen clients from 21 sites in New York City was conducted simultaneously with the food pantry study.[5] A random sample of kitchens was drawn from the Bureau of Nutrition census.[2] Within each site, clients were identified through a random sam-

pling procedure while waiting in line, but the interviews took place either before or after eating with as much privacy as possible. Interviewer selection and training were similar to the food pantry study.[5] The numbers of meals served by each site ranged from a few to 209,000 annually. As with the pantries, large and small sites were appropriately represented in the sample.[5]

Results

Eighty percent of clients had used soup kitchens for less than a year; the remainder were long-term users. Table 1 summarizes other characteristics of soup kitchen users in our sample. Compared with the general population of not homeless persons living below the poverty line in New York City[6] the soup kitchen users we studied were overwhelmingly male, disproportionately African-American, not elderly, and far more likely to live alone. Among those who did live with others, soup kitchen users (both homeless and not homeless) were much less likely than members of the general poverty population to live in households with children.

Compared to the not homeless, the homeless (the 41 percent of our sample who lived in shelters, or in the streets, or "no one place") were more likely to be male, younger, Hispanic, living alone, and unemployed. Fully 47 percent of them had no income.

Twenty-two percent of the entire sample earned wages (Table 2) and there was no significant difference on this between homeless and not homeless. Twenty-nine percent of the sample received welfare benefits, and the homeless were significantly less likely to receive assistance, including SSI and Social Security. The median monthly per capita income (calculated without food stamps) of the entire sample was $120, with 61 percent of them below 50 percent of poverty. The

[b] Food Stamp Users vs Non-Users; Chi-square (df=2)

median monthly income of homeless respondents was $12 (Table 3) and 80 percent had incomes below 50 percent of the poverty level.

Approximately 30 percent of respondents received food stamps. Significantly more of the not homeless participated in the program (Table 1) but, among the homeless, there were no significant demographic differences between food stamp users and non-users (Table 4). In the not-homeless population, significantly fewer recipients lived with others, or in households where someone was employed (Table 4). The average monthly per capita food stamp benefit was significantly higher for the homeless recipients ($73 vs $40, t=−5.087, p=0.0001), undoubtedly reflecting their lower incomes.

Discussion

Comparison of this study with the few recent non-random studies,[7,8] the 1987 study of upstate New York soup kitchen clients,[4] and our food pantry study[5] was done to corroborate the extent of the problems being faced by low income persons. Except for a greater percentage of White clients, data gathered by the Human Resources Administration in 1986 are virtually identical to ours with respect to percent of males, age distribution, homelessness, lack of income, and receipt of public assistance, specifically SS and SSI.[7]

The biggest difference between soup kitchen clients in our NYC sample compared to Upstate clients[4] was the percentage of homeless (41 percent in NYC and 17 percent Upstate). Homelessness in NYC was also reflected in other differences: less use of food stamps, housing subsidies, and health insurance. The NYC clientele was younger, and many fewer received Social Security. More clients Upstate (more of whom were female) were disabled, retired, and received welfare benefits (AFDC, Home Relief) or SSI.

When NYC soup kitchen clients were compared with NYC food pantry users studied at the same time,[5] there were expected differences in age, ethnicity, and homelessness. The educational level was higher among soup kitchen respondents. Significantly fewer soup kitchen clients utilized food stamps or Medicaid, but there were no significant differences in the use of child nutrition and senior feeding programs.

There was a highly significant difference in the percentage of soup kitchen clients who had no income (29 percent) compared to food pantry users (8 percent). Since 88 percent of homeless soup kitchen users received no public assistance, 80 percent received no food stamps, and 79 percent had no health insurance, the precariousness of their lives is evident. A recent report from the National Academy of Sciences documents the fact that homeless people suffer more illnesses and injuries and are at greater risk for a variety of health problems including malnutrition.[9] Soup kitchen clients often eat only once or twice per day and soup kitchen meals tend to be nutritionally inadequate.[10]

Most of the clients in soup kitchens are obviously eligible for public assistance but do not receive it. Many have been unable to meet paperwork requirements; recommendations have been made for reducing these barriers so that more people can receive benefits.[6] However, full public assistance payments will not cover housing costs for most clients. The New York State courts have recently ruled that the Commissioner of Social Services must establish housing allowances that bear a "reasonable relation" to housing costs.[11] For many soup kitchen clients, adequate housing subsidies would provide more funds for food. For others, who are alcohol or drug abusers, other programs are necessary. In the meantime, the need for meals is growing and the size of the problem is too large to be met by the uncoordinated, largely voluntary Emergency Feeding System. ☐

Farm Tractors and Mandatory Roll-Over Protection Retrofits: Potential Costs of the Policy in New York

Timothy W. Kelsey, PhD, and Paul L. Jenkins, MS

ABSTRACT

Tractor roll-overs are the leading cause of fatal farm accidents, accounting for more than one-fourth of all agriculturally related deaths. Most of these deaths could be prevented if the tractors were equipped with roll-over protective structures (ROPS). This study estimates the number of tractors in New York without ROPS, projects their retirement, and then estimates the number of lives which would be saved if ROPS were retrofitted on old tractors. The basic costs associated with mandating ROPS are calculated from these estimates. The minimum economic cost of mandating ROPS is $511,136 per life saved for the retrofits, and an additional $253,254 per life saved for every $1 million spent annually on enforcement. It is concluded that a policy mandating ROPS on all tractors would be expensive, but should be considered with particular attention to the need for and cost effectiveness of enforcement. (*Am J Public Health*. 1991;81:921–923)

Introduction

Agriculture consistently has one of the highest fatal accident rates of any occupation,[1] and tractor roll-overs play a prominent role in such accidents. Tractors are associated with about 50 percent of fatal agricultural accidents,[2] with roll-overs typically accounting for over half of these.[3-6] Evidence from Sweden suggests that most of these roll-over fatalities could have been avoided if the tractors involved had been equipped with roll-over protective structures (ROPS) to prevent operators from being crushed by an overturn.[7]

Most farm tractors in the United States lack ROPS, with only 19 percent of tractors in Pennsylvania[6] and 15 percent in one New York county* so equipped. ROPS became available in the 1960s, but did not become standard equipment on many tractor models until the late 1970s and early 1980s. In 1985, manufacturers voluntarily agreed to make them standard equipment on all new tractors.

Various proposals have been made to make ROPS mandatory in the US.[4,8] This study analyzes the National Coalition for Agricultural Safety and Health (NCASH) proposal to offer farmers retrofit incentives for five years and require ROPS on all tractors after 10 years. The potential economic cost per life saved from such a policy in New York is estimated using cost-effectiveness analysis, a common approach to appraising public health policies.[9-15] The cost shifting effects of incentives are not addressed in this analysis because of the study's economic (as opposed to financial) focus.

Methods

There are few available data on the age distribution of tractors currently on US farms or their ROPS status. The magnitude of the effect of ROPS in reducing the number and severity of non-fatal injuries is uncertain, especially when the operator is not wearing a seat belt, although anecdotal evidence suggests almost all deaths are prevented.

For this study the potential number of tractors which would be retrofitted in New York State was estimated by interpolating from US Census of Agriculture, Farm and Industrial Equipment Institute, and Pennsylvania tractor data, using the 4 percent retirement rate implied by data in the Census of Agriculture. There are no available data about the percentage of tractors of different ages in New York without ROPS, so the results of a survey in Pennsylvania by Huizinga and Murphy[6] had to be used. The geography, agricultural production, and economic situation of farmers in Pennsylvania and New York are roughly similar, making their data a relatively good approximation for tractors in New York. A total of 59,873 tractors would need to be retrofitted according to these calculations. It was assumed that all tractors covered by the 10-year requirement would be retrofitted during the first five years of the program, when the incentives are in effect (see Figure 1).

An average of nine people a year die from tractor roll-overs in New York State.** The number of deaths which would be averted by the retrofit policy was estimated by combining this with the current percentage of tractors without ROPS and the estimated pace of retrofits, under

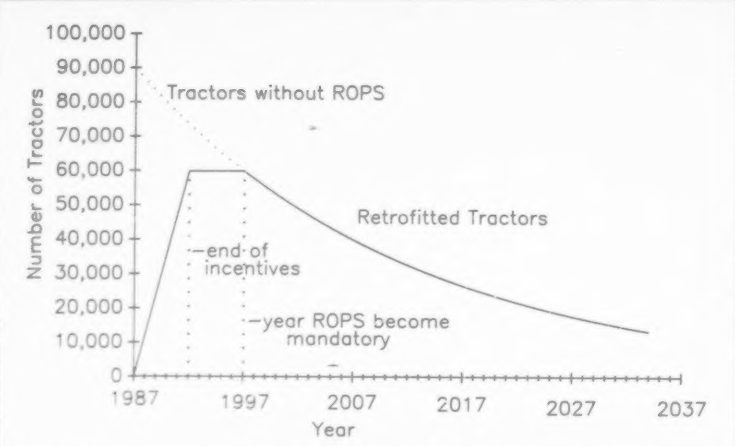

FIGURE 1—Estimated Number of Tractors Originally Manufactured Without ROPS Operating in New York if ROPS Became Mandatory on all New Tractors

TABLE 1—Cost Per Life Saved

	Cost Per Life Saved*	
Life-Saving Effectiveness of ROPS	For ROPS	For Every $1 Million Spent Annually on Enforcement
75 Percent	$684,729	$337,672
100 Percent	$511,136	$253,254

*Discount rate = 5 percent

two alternative assumptions about the life-saving effectiveness of ROPS; 100 percent and 75 percent.

The costs of such a policy would include enforcement, as well as purchase and installation of the ROPS. Without enforcement there is no guarantee that all tractors will be retrofitted or that retrofitted ROPS will not later be removed. In Pennsylvania, 38 percent of the tractors manufactured since 1986 do not have ROPS, even though beginning that year tractors without ROPS were sold only under special circumstances. This occurred in part because farmers removed the ROPS after purchasing the tractor.[6] The reasons for removals have not been comprehensively studied, although the inability to operate a ROPS equipped tractor in buildings with low ceilings is a common explanation. The costs of enforcement can be significant, but because the NCASH proposal lacks an enforcement plan such costs will not be directly integrated into the analysis.

The specific cost of retrofitting tractors was determined by calling five ROPS manufacturers and wholesalers, including John Deere, Inc, and Ford/New Holland. The contacts indicated that increased sales would not affect most prices. The average uninstalled retail price reported for most ROPS was $632, which means the average final per unit cost will be approximately $700 with installation. The present value of all the retrofits was calculated assuming that the retrofits occur evenly throughout the five-year incentive period. Both costs and the lives saved were discounted with a 5 percent discount rate.

Results

A policy mandating ROPS in 10 years requiring any tractor in New York to have ROPS to be operated and providing economic incentives for retrofits during the first five years of the program could have a total ROPS cost of approximately $36.3 million. The present value of lives saved would be 53 or 71, depending upon the life-saving effectiveness of ROPS. The costs per life saved under the different scenarios are in Table 1. If perfect compliance does not occur and fewer lives are saved, the enforcement cost per life saved would be higher.

Discussion

These estimates of cost do not include consideration of the effectiveness and cost of enforcement. In addition, the model of tractor retirements biases the number of lives saved upwards. Another upward bias in estimation of the lives saved is that we could not include the natural reduction in farmers' exposure to risk over the years as tractors are slowly shifted from field work to more stationary roles and their hours of use decrease. Finally, non-pecuniary aspects of requiring ROPS retrofits are not included in these estimates.

Based on the projected cost without enforcement, ROPS would be similar to other life-saving interventions, but the need for enforcement could drastically increase cost. One reviewer found costs less than $1 million for auto safety standards and greater than or equal to $3 million for most efforts to regulate toxic substances.[16] Graham and Vaupel reviewed 35 studies of life-saving programs, and found the cost per life saved ranged from no cost for compulsory seat belt use, $60,000 for mandatory smoke detectors, $255,000 for the 1966 Motor Vehicle Safety Act, $408,000 for mandatory air bags, and $1,200,000 for the 55 mph speed limit, to over $3,500,000 for policies regarding toxic substances.[17]

Mandating ROPS retrofits is worth considering because of its life-saving impact, but enforcement must be directly and carefully debated because the policy impact will depend so much upon it and because enforcement could easily be the largest expense. In any event, a retrofit policy will not be cheap. ☐

The Use of Direct Mail to Increase Clinician Knowledge: An Intervention Study

Donald Sadowsky, DDS, MPH, PhD, and Carol Kunzel, PhD

ABSTRACT

A probability sample of American general practitioner dentists, 40 years of age or older, in solo private practice, was the target of two direct mail interventions offered at two different times, to test whether knowledge regarding prophylaxis of patients at risk for infective endocarditis could be improved. Tests of knowledge were responses in a mail questionnaire to clinical vignettes, designed to elicit the content of antibiotic regimens used for patients at risk. The research design enabled detection of (1) the effect of the interventions; (2) the differences in their effect; (3) the attenuation of their effect; and (4) the effect of time. Where baseline knowledge was low, it was improved and did not rapidly disappear. Both mail interventions were equally effective, in most instances, and there was no attenuation of the interventions' effect and no effect of time on the control groups' knowledge over a 4½ month period. The results suggest that it is possible to improve clinicians' knowledge of expert recommendations through direct mail intervention. (*Am J Public Health.* 1991;81:923–925)

Introduction

Direct mail has been used relatively infrequently, except by the pharmaceutical industry, to "market" ideas to clinicians. The results of several studies[1-7] testing the efficacy of mailed information in improving clinicians' knowledge are equivocal. Moreover, the effects of these efforts are often difficult or impossible to discern because of the absence of a sound experimental design.

Since the mid-1950s, the American Heart Association (AHA) has been trying to inform physicians and dentists about the details of a variety of antibiotic regimens that have been determined to be efficacious in the prevention of infective endocarditis, depending on the risk factor and the procedure to be performed. As the state of the art has changed, these AHA recommendations have been revised.[8-13] Dentists have been a target group for this AHA program because any procedure that produces mucosal bleeding may produce a transient bacteremia which, in turn, may seed a heart valve previously scarred by, for example, rheumatic heart disease. The ultimate sequela of this series of events may be infective endocarditis.

Our project had four aims: (1) to determine whether simple inexpensive mail interventions could be designed to improve the knowledge of dental general practitioners (GPs) about the management of patients at risk for infective endocarditis; (2) to design two interventions, one with a theoretical component and one without it, to determine whether the additional material would have an additional effect; (3) to determine whether the effects of the interventions, if any, would be maintained over time; and (4) to determine whether clinicians' knowledge would change over time, independent of the planned interventions.

Methods

After a probability sample of 1148 dentists, classified as GPs, 40 years or older, in private practice within the continental United States, was drawn from

$^{+}$ Knowledge Level of All Six Groups Assumed Equal at Time Zero

FIGURE 1—Groups (Each group is representative of solo US GPs, 40 years or older and in private practice)

the American Dental Association's master list containing names of all dentists in the United States, the list was cleaned and criteria for eligibility were ascertained via postcards. Remaining potential respondents (686 GPs, 40 years of age and older, in solo private practice*) were randomly assigned to one of six experimental conditions. An overall response rate of 87.20% was achieved.

Four groups were contacted at baseline time zero (Fig 1). Two of these groups received a laminated placard (intervention 1), containing AHA information.[17] The reverse side of the placard was blank. The other two groups received the same placard but with 11 statements on the other side providing information about the theoretical underpinning of the AHA recommendations (intervention 2) with the expectation that enhancing understanding might help increase knowledge.[16] All placards were mailed with a cover letter encouraging the ongoing use of the placard as a resource in the office setting. Knowledge is used in this article to indicate availability of information. The remaining two groups (controls) were not contacted at time zero.

At time 1, 4½ months later, members of one control group, one group who had received intervention 1, and one group who had received intervention 2 were mailed an 8-page data collection instrument, along with a cover letter and a check for 10 dollars. At time 2, 4½ months after time 1, the same procedures were repeated for a second control group, for another group who had received intervention 1, and for a second group who had received intervention 2.

A precoded, forced choice, data collection instrument used varieties of clinical vignettes to elicit information. Dentists were asked to indicate the content of the antibiotic prophylactic regimen they might prescribe or administer for patients at different types of risk. Answers to questions about different patient conditions were assessed as "correct" = 1; "incorrect, unsure" = 0; "blank" = missing, using the standard of the most recent (at the time of the study) AHA recommendations. The resultant 0–1 dichotomous variables were analyzed as a special case of proportions, using either three-group or two-group χ^2 tests. The Yates correction was used for all two-group comparisons. SPSS/PC was used to perform all statistical computations.

Results

There was no significant attenuation in knowledge from one time period to the next in groups receiving the interventions, and knowledge scores remained stable over time in the control groups.

Because analyses indicated that time itself had no effect on knowledge scores, data for both control groups, for both intervention 1 groups, and for both intervention 2 groups were combined to ascertain the net effect of the interventions. χ^2 analyses contrasted the proportion of correct answers in the three types of experimental groups. Results indicate that, with the exception of the valvular heart disease patient, experimental group membership had a statistically significant impact on the proportion of correct answers about regimen components, as well as a statistically significant impact on correct answers about bacteremia duration, an important theoretical variable underlying the recommendations (Table 1).

There were no statistically significant differences between the two interventions for knowledge about the prosthetic heart disease patient, the child valvular heart disease patient, and the prosthetic heart valve patient with a penicillin allergy. Intervention 1 did not affect correct knowledge of managing the patient on a continuing antibiotic regimen and of bacteremia duration. However, intervention 2 had a statistically significant impact on both these knowledge items.

Discussion

The relative absence of an effect from the addition of scientific justifications for the AHA recommendations (intervention 2) can perhaps be explained by the findings of a comprehensive study by the RAND Corporation,[18] i.e., that consensus statements "are more likely to be effective if they are succinct, didactic, and oriented toward a clinical rather than a scholarly audience." The RAND study also provides a likely explanation for the uneven effects of the interventions: the negligible effect of the interventions on knowledge about the management of patients with a history of valvular heart disease is probably accounted for by the relatively high knowledge about antibiotic management of patients with this particular risk factor before the interventions. In reverse, this may also be a partial explanation for why knowledge about both the management of children and about patients with prosthetic heart valves improved considerably: for these conditions, baseline knowledge was very low and there was an opportunity for a great deal of improvement.

The improved knowledge scores of groups receiving intervention 2, on items about bacteremia duration and the man-

---

*Eighty percent of American dentists are GPs[14] and, on a test of knowledge of endocarditis prevention, they scored dramatically lower than a cohort of dental specialists.[15] Also, dentists in solo general practice, 40 years or older, are most likely to be deficient in knowledge about the proper management of patients at risk for infective endocarditis.[16]

agement of patients on a continuing antibiotic regimen, can be explained by the theoretical nature both of these items and of the intervention.

The experiment described provides evidence to support the notion that it is possible to improve clinicians' knowledge through direct mail intervention and that the effect does not rapidly disappear. More work must be done before the conditions under which this can be accomplished will be specified with any precision. Our study may provide some helpful hints about what works and what does not work. ☐

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health*, 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Service Needs of Severely Disturbed Children

ABSTRACT

Background: As one piece of a statewide Children's Mental Health System Analysis conducted in Washington State, the specific service needs of severely emotionally disturbed children were investigated.

Methods: The primary caseworkers of 3398 children under the care of the state responded to a survey of the child's treatment history, social and clinical condition, and service needs. Service need data on the 2455 children in the sample who were classifiable as severely emotionally disturbed were examined using log linear analysis.

Results: School- and home-based services were frequently reported needs of school-aged children. Adolescent children were reported to be in need of services which prepare them for adulthood. Services endorsed for female children tended to focus on assistance to family members, therapy, and protection, whereas services endorsed for male children focused on home removal, substance abuse treatment, and preparation for employment.

Conclusions: Severely emotionally disturbed children are in need of a variety of nontraditional mental health services. Significant differences in the needs of male versus female children, and of differently aged children, are present that have serious implications for service system development. Eric W. Trupin, PhD, Amy Forsyth-Stephens, MSW, and Benson P. Low, PhD

Introduction

The treatment needs of severely and chronically mentally ill individuals, of any age, vary considerably depending upon personal characteristics (e.g., degree of disability, nature of symptomatology, willingness to accept treatment), and situational or environmental characteristics (e.g., availability of natural supports, residential situation, mobility of the individual). Ideally, the range of available services would be so broad, and care givers so flexible, that all clients would receive an appropriate, individualized menu of services. Unfortunately, human services, especially mental health, are largely program-driven, with clients matched to programs, rather than services matched to clients. Given that this infrastructure of care provision may be difficult to overturn, it is imperative that the development and design of state and local programs be based upon a concrete knowledge of client needs.

Services for children* are especially subject to "blind" planning and implementation. There is a dearth of research in the area of children's mental health, most notable on the topic of severely mentally ill children.[1] Analogous to the study of chronic mental illness among adults, the area of severe emotional disturbance (SED) among children is a relatively recently established field of research. Attention was drawn to the issue in 1982, when the unsettling book *Unclaimed Children*[2] reported that two-thirds of all SED children do not receive the services they need.

The book went on to document the failure of federal and state governments to acknowledge and attempt to meet the mental health needs of children, resulting in a vast and deeply troubled population with no advocacy, options, or hope. Five years later, the Office of Technology Assessment of the United States Congress[3] underscored accusations put forth in *Unclaimed Children.*

In 1984, the National Institute of Mental Health initiated the Child and Adolescent Service System Program (CASSP) in an effort to address the national crisis in children's mental health.[4] The goal of CASSP was, and continues to be, the promotion of system development through the funding of 40 state-level planning initiatives and two national research centers for the study of SED among children.

Most of the research to date on service needs of SED children has been produced by state human service departments in response to legislative mandates or class action suits, or by CASSP-funded research institutes. Based upon work completed by many states, and by the CASSP research centers, an assumption has been promulgated that a complete range of services, on a continuum from most to least restrictive, must be developed to adequately meet the needs of severely emotionally disturbed children.[5] Most recently, the "continuum of care" idea has been replaced by the concept of a "system of care" for SED children,[6]

Trupin, PhD, Division of Community Psychiatry, Department of Psychiatry & Behavioral Sciences, School of Medicine, University of Washington, Mailstop RP-10, Seattle, WA 98195. This paper, submitted to the Journal July 9, 1990, was revised and accepted for publication January 23, 1991.

*In this article, "Children" refers to anyone under the age of 19 years.

which has a somewhat broader connotation. With the system perspective, more than a comprehensive spectrum of appropriate services is necessary. Just as critical are the underlying facilitating mechanisms, structures, and administrative processes to ensure that services are delivered and received in a coordinated, child-focused manner.

There have been no empirical studies of the diverse service needs of severely emotionally disturbed male children versus female children. Similarly,there have been no reports of service need data by developmental groupings (i.e. young children, preteens, and adolescents). Only one report has documented the age and sex breakdowns of an SED child population. In North Carolina, Behar[7] reports that the population of children qualifying as SED was 80 percent male, 20 percent female. Over three-fourths (78 percent) of the SED children were between the ages of 12 and 17; 14 percent were under the age of 12.

This paper presents the findings of a statewide survey of the specific service needs of 1617 severely emotionally disturbed children. The large sample size of the survey permits analysis of service need data by age and sex categories. The possibility of identifying distinct ideal service continuums for male and female SED children of various age groups is discussed.

Method

Design

The survey of service needs of SED children took place in the context of a broader study of the children's mental health system in Washington State. This larger project, entitled the Children's Mental Health System Analysis, involved the administration of a Child Mental Health Survey to adult care takers of randomly selected, nonidentified children served by the Department of Social and Health Services (DSHS).

The analysis of data occurred in two stages. The first stage involved the identification of children in the sample who were classifiable as SED (this procedure is described below under "Classification of Children as SED"). The second stage involved the examination of reported service need data for the subjects who were classified as SED according to our model.

A significant design feature was the nonidentified status of children surveyed. Use of identified data would have required informed consent for every child in the survey. Apart from the logistic demand such a requirement would have brought, institutional or agency refusals would have become a significant problem. While the use of nonidentified data facilitated more comprehensive surveying of children, it did limit control over the subject selection process, and precluded empirical analysis of subject attrition.

Subjects

The subjects were 3,398 children and adolescents ages 0 to 18 who were selected randomly from the billing rosters of child-serving programs within the State's Department of Social and Health Services (DSHS). Nearly half of the subjects (N = 1,640) were clients of the DSHS Division of Children and Family Services (DCFS), which offers an array of child welfare services including child protective services, foster care, group home care, in-home intervention, and emergency out-of-home placement. The remainder of the sample was made up of clients of the DSHS Division of Juvenile Rehabilitation (DJR; institutions, group homes, and parolees; N = 1,035); the DSHS Mental Health Division (DMH; inpatient, residential, day treatment, and outpatient; N = 524); and the DSHS Division of Developmental Disabilities (DDD; institutions and group homes; N = 199).

Sample sizes were calculated by taking into consideration the population size, the *a priori* estimate of the rate at which SED would occur (50 percent in all DSHS groups), the range of the intended confidence interval (+5 percent), and the probability level for the confidence interval (95 percent). Sample sizes were inflated by a factor of 15 percent, to compensate for subject attrition. As an exception, the DSHS Division of Juvenile Rehabilitation made an administrative decision to survey all clients in their programs. All clients in programs with caseloads of fewer than 150 were surveyed.

Respondents

The survey respondents were 3,398 adult DSHS professionals or staff members of agencies under contract with DSHS. Two-thirds of the respondents (65 percent) were case workers or facility staff employed either directly by DSHS, or by a contracted agency. The remaining one-third was made up of probation/parole officers and independent mental health professionals. Ninety-two percent of the respondents had at least a four-year college degree. The mean length of time that a respondent had known the surveyed child was 12.2 months.

Survey Instrument Development and Reliability

The data collection instrument, entitled the Child Mental Health Survey,* was developed after review of materials used by other states in similar but smaller-scale efforts.[8] The survey instrument contained six sections with questions pertaining to: 1) sociodemographic background; 2) exposure to 13 mental health risk conditions; 3) current behavioral adjustment as measured by the Child Behavior Checklist (CBCL);[9] 4) past mental health treatment and placement history; 5) other handicapping conditions; and 6) mental health and social service needs. The section on service needs required the respondent to identify the subject's past receipt, current receipt, and current unmet need for any of 32 human services.

The Child Mental Health Survey was administered to pairs of teachers of 26 special education pupils and 30 regular education pupils, and to pairs of case workers of 10 children placed in mental health treatment programs in the community. Each of the respondents independently completed surveys on the selected child. Reliability coefficients were calculated on four sections of the survey: exposure to mental health risk factors, mental health treatment history, other handicaps, and current behavioral adjustment. The Kappas obtained for the sections on risk factors, treatment history, and other handicaps were in the acceptable and expected range, with most values above .60, and some exceeding .80.[10]

Reliability coefficients were not calculated on service need data. Interrater reliability was less of a concern for the service need data, as the caseworkers who completed the survey forms were highly face valid, as they are the "natural" raters who drive the system of referrals for these SED children. Moreover, a meta-analysis on concordance of raters of children underscores that data from a single respondent typically provide a reasonable sample of what would be provided by other informants of the same type who see the child under generally similar conditions.[10]

Classification of Children as SED

SED children from the sample were identified via MANOVA techniques.

---

*The Child Mental Health Survey is available from the first author upon request.

Each subject was treated as a group of one and then compared via Hotelling's T^2 against a criterion SED group. The criterion SED group was defined as all children being served in the State's psychiatric residential treatment centers, and a specialized foster care program for previously psychiatrically hospitalized children. These programs provide the most comprehensive, intensive, and expensive mental health treatment offered by the state mental health system for children. It was the research team's consensus that children meeting the numerous requirements for admission to these programs are inarguably severely emotionally disturbed, and therefore comprise the most valid, conservative, and defensible criterion group for this study.

Each subject was evaluated individually as to the likelihood of being drawn from the criterion group. If the subject was discriminable, the subject was not classified as SED. The independent variables used in the discriminant analysis were: 1) *Mental Health Risk,* scored as the number of risk factors endorsed positively for the subject; 2) *Chronicity,* scored as positive if the subject was rated as experiencing severe aggressiveness and/or withdrawal for a minimum duration of one year; 3) *Service Need,* scored as the number of mental heath services endorsed as "needed" or "currently received"; 4) *Internalizing Behavior Problem,* which was the T-score from the CBCL Internalization Scale; and 5) *Externalizing Behavior Problem,* which was the T-score from the CBCL Externalization Scale. These five measures are widely used and face valid with respect to the detection of the presence of an emotional or behavioral problem in children.[11–14]

Service Need Data Analysis

Service need data were analyzed for those children classified as SED according to the above model. Data on the services indicated as "needed" by SED children were weighted by DSHS population estimates of SED children across age and sex categories. This was done in order to control for the varying age and sex distributions of the four subsamples (i.e. DCFS, DJR, DDD, DMH). The population estimates were based upon the prevalence distribution of SED in our subsamples. A log linear analysis technique was used to test for significant differences in service need among three age groups of SED children (6–11, 12–16, and 17–18 years), and between male and female SED children.

Results

Survey Return Rates

The overall DSHS survey return rate was 75 percent (i.e. 4,516 surveys were distributed, 3,398 were completed and returned). Return rates for the various participating divisions of DSHS ranged from a high of 95 percent for DJR to a low of 66 percent for DCFS. The high overall survey return rate was primarily a function of consistent DSHS involvement with the design and execution of the study. Most supervisors at local DSHS offices required 100 percent survey completion by their caseworkers, and actively monitored this assignment. Additionally, researchers distributed two reminder notices to DSHS supervisors during the time frame allotted for survey completion. All respondents were assured of, and received, feedback on the outcome of the survey.

Service Needs of SED Children

Of our sample of 3,398 children, 2,455 were classified as SED according to our model (described above, $\alpha = .10$). Of these 2,455 SED children identified from our original sample, data on 1,617 were used in this analysis of service needs. A total of 838 cases were eliminated due to the subject's age (less than 6 years) and/or an incomplete survey form. Children ages 0 through 5 were not included in this analysis due to the small size of that subsample ($n = 96$). Table 1 reports the estimated percent of the DSHS SED population needing various mental health and social services.

Across all age and gender categories, over one-half of all SED children needed outpatient mental health treatment (defined as individual, group, or family therapy). Nearly one-half of SED children's families were in need of family support services for the parents and/or siblings. Interagency case management was needed by nearly one-third of SED children statewide. Other services which were commonly needed included school-based mental health services and psychological testing. Of all residential/inpatient services, foster home placement and group home placement were the most commonly reported service needs.

Age and Gender Service Need Differentials

Fourteen of the 32 possible mental health and social services listed on the Child Mental Health Survey showed significant differences in reported need across the three age groups. These are displayed in Table 2.

School children from age 6 through 11 (Group 1) were significantly higher than all other age groups in the need for respite care for their family members (11.0 percent, $p < .000$), and for therapeutic camp services (17.7 percent, $p < .000$).

Children in Age Groups 1 and 2 (ages 6–11 and 12–16) displayed a higher need for school and home-based services than older SED children, specifically school-based mental health services (Group 1: 30.0 percent; Group 2: 27.4 percent), supervised after-school activities (Group 1: 20.3 percent; Group 2: 18.0 percent), and intensive in-home therapy (Group 1: 15.6 percent; Group 2: 18.8 percent).

Children ages 12 through 16 (Group 2) were reported as more in need of foster home placements (18.9 percent, $p < .001$) and group home placements (12.6 percent, $p < .000$) than children in other age brackets. Data show that the need for both of these services peaks in the years 12 through 16, although the need pattern for the two services is quite different across the full developmental range. The need for foster home placement is high (12.3 percent) even within the 6 to 11 year old age group, and grows in the 12 to 16 year old group. At that point the need declines to 11.1 percent in the 17 to 18 year old age group. Group home placement, however, is low for the 6 to 11 year old age group, and then rises dramatically for the 12 to 16 year olds, staying relatively high (11.3 percent) for the 17 to 18 year old group.

Older adolescents (Group 3, ages 17–18) demonstrated a significantly higher need for outpatient alcohol or drug treatment (31.4 percent, $p < .000$), and inpatient alcohol or drug treatment (15.6 percent, $p < .000$) than the other age groups. They also demonstrated a much greater need than other age groups for training in independent living skills (58.6 percent, $p < .000$), vocational services (49.2 percent, $p < .000$), and supervised independent living arrangements (28.5 percent, $p < .000$). For each of these services, the expressed need was nonexistent or extremely low for younger children (ages 6–11), increased for children ages 12 through 16, and peaked for children 17–18 years of age.

Significant sex differences in endorsement of service need were identified among 11 of the 32 service types contained on the Child Mental Health Survey. These differences are also reported in Table 2.

Females were significantly higher than males in their reported need for out-

patient therapy (61.7 percent, p < .000), foster home placements (19.1 percent, p < .001), respite care (8.0 percent, p < .000), supervised independent living arrangements (7.6 percent, p < .001), and child protective services referral/intervention (9.6 percent, p < .000).

Males were rated as having a significantly greater need for outpatient alcohol or drug treatment (16.2 percent, p < .000), inpatient alcohol or drug treatment (7.9 percent, p < .000), group home placement (10.6 percent, p < .000), training in independent living skills (19.0 percent, p < .000), and supervised afterschool activities (19.8 percent, p < .006).

Discussion

Our survey of the professional caregivers of SED children generated a useful data base on the service needs of this population. While previous research and program planning efforts have identified only general categories of services appropriate for SED children, this broad-based study is the first to produce quantitative data on the extent of the SED population reported to be in need of a wide range of mental health, health, social, and support services. It is also the first study that further defines age and gender differences in types of needed services.

Overall Patterns of Service Need

Across age and sex groupings, the most frequently reported needs, in descending order, were for: 1) outpatient therapy; 2) family support groups; 3) intersystem case management; 4) school-based mental health services; 5) psychological testing; 6) training in independent living skills; 7) intensive in-home therapy; and 8) supervised after-school activities. With the exception of outpatient therapy and psychological testing, all of these services would be considered "non-traditional" mental health services, or even outside the realm of mental health altogether.[6]

We had anticipated that our survey of professionals would result in a high expressed need for residential or inpatient services, since respondents' level of familiarity with other more progressive treatment approaches was questionable. We reasoned that direct care providers might be hesitant to endorse non-traditional services as needed, especially if such services were not accessible to them.

Clearly, this was not the outcome. The strong presence of CASSP in Washington State may be credited for a good

deal of the progressive thinking of the state's professional care givers through conferences, newsletters, and an intensive effort to begin the creation of local intersystem case coordination committees. Not recognizing the significant impact of these educational efforts, we underestimated the knowledge base of our respondent pool.

Unfortunately, Washington State's current service system reflects the national reality, in that treatment resources continue to be focused on a proportionally small number of children who receive care on inpatient psychiatric units or other intensive residential treatment programs.[3,15] Our data support the direction of CASSP-funded research and training centers and the National Mental Health Association in the endorsement of less restrictive home and school-based services, family support services, and comprehensive case management services as alternatives to costly out-of-home care.[15,16]

Age and Sex Differences

Service planners generally tend to think of SED children as one class of service recipients. Our data suggest that there are significant differences in the service needs of male versus female children, and of differently aged children. These differences have serious implications for the development and implementation of systems of care for the SED population.

Our data demonstrate a substantial developmental gradient which must be considered when planning services for SED children. For school-aged children the educational setting clearly should play a large role in treatment planning. For example, school-based mental health services and supervised after school activities were distinct needs of 6–16 years olds. Therapeutic camp services and foster home placements were also highly endorsed for this subset of SED children.

For the 17–18 year old group, there is a great need for services which prepare youth for the transition for adulthood, such as training in independent living skills, vocational services, and supervised independent living arrangements. The need for outpatient and inpatient alcohol/drug treatment also peaks for this age cohort.

Sex differences in service need were less obvious than the developmental differences. Males demonstrated a greater need for transitional "adult" services, for alcohol and drug-related treatment, and for group home placement. Females, on the other hand, were in greater need of outpatient therapy, foster home placements, respite care for their families, supervised living arrangements, and protective services. The services endorsed for males focused on home removal, treatment of addiction, and preparation for entry into the work force. Services endorsed for females focused on therapy, assistance to the girls' families, and protection from further harm. More research is needed to confirm whether these gender-linked service needs are valid indices of what SED children need in their treatment, or merely reflections of sex-based stereotypes of SED children's vulnerabilities and responsiveness to various treatments and interventions.

TABLE 2—Significant Age and Gender Effects

Service	Direction of Effect
Age Main Effects	
Therapeutic preschool	1 > 2,3
Respite care	1 > 2,3
Therapeutic camp	1 > 2 > 3
Transportation to needed services	1,2 > 3
Intensive in-home services	1,2 > 3
School-based mental health services	1,2 > 3
Foster home placement	1,2 > 3
Supervised after school activities	1,2 > 3
Group home placement	2,3 > 1
Outpatient alcohol/drug treatment	3 > 2 > 1
Inpatient alcohol/drug treatment	3 > 2 > 1
Training in independent living skills	3 > 2 > 1
Vocational services	3 > 2 > 1
Supervised independent living arrangement	3 > 2 > 1
Gender Main Effects	
Outpatient therapy	F > M
Foster home placement	F > M
Respite care	F > M
Supervised independent living arrangement	F > M
Child protective services	F > M
Outpatient alcohol/drug treatment	M > F
Inpatient alcohol/drug treatment	M > F

Study Limitations

Limitations of this study lie in its narrow focus on professional respondents, the non-random nature of the final sample, and the survey's exclusion of preventive services.

First, our survey respondents were exclusively the professional care givers of SED children. This clearly provides only one perspective on what a given child's treatment needs may be. Family members, school personnel, and other persons in the child's support circle are equally valid respondents. Nevertheless, given that the focus of the survey was on SED children who were "system veterans" with well-known and extensive patient histories, input from the primary professional care givers was a good starting point. This in no way precludes the need to vigorously solicit the participation of parents and teachers in the development of individual children's treatment plans and larger scale planning endeavors.

Second, for the analyses of service need data, the ultimate data base of SED children was a nonrandom approximate 50 percent of our original random sample of children. Cases were eliminated for three possible reasons: 1) the survey form was not returned; 2) the survey form was returned, but was missing critical information; or 3) the child was under 6 years of age. Ideally, our final sample would have been of a completely random nature. However, because the subjects were unidentified to the investigators, and since no special services were offered to children as a result of survey responses, the final sample appeared not to be biased systematically. Case worker-related factors, such as excessive paperwork demands, rather than child-related factors, appeared to contribute to the rate of subject loss.

Third, because children who were already classifiable as SED were the subjects of this study, primary preventive services were completely excluded from the range of services offered as possible service needs on our data collection instrument. Readers must keep in mind that the services highlighted as "most needed" by our survey represent the narrow but critical range of mental health and other services for those children who are already identified as SED. Services such as community education, parent training, teen parenting classes, substance abuse prevention, advocacy, early childhood intervention, etc., are very important elements of a comprehensive strategy to combat severe childhood mental illness. ☐

Analysis of US Child Care Safety Regulations

Carol W. Runyan, MPH, PhD, Diana E. Gray, MPH, Jonathan B. Kotch, MD, MPH, and Matthew W. Kreuter, MPH

ABSTRACT

Background: With 1.9 million US children cared for in organized group child care, the safety of these children is a public health concern. In the absence of federal policy, each state has developed its own day care safety regulations.

Methods: After creating a set of 36 criteria from three sets of national guidelines, we assessed the safety regulations of 45 states. With a mailed survey of state day care regulatory personnel, we examined the processes of formulating and implementing safety policy in 47 states.

Results: For 24 of the 36 items, more than half the states' regulations were below the criteria or failed to mention the topic. Most notable is the inattention to playground safety, choking hazards, and firearms.

Conclusion: The uneven quality of regulations may be a reflection of a regulatory process that is fragmented, with many different groups sharing authority and with limited involvement of injury prevention specialists. (*Am J Public Health*. 1991; 81:981-985)

Introduction

According to data from the winter of 1984–85, 1.9 million United States children of working mothers were cared for in organized group day care, and an additional three million received regular care in private homes other than their own.[1]

The importance of injuries to preschoolers is well-documented,[2–4] as are the patterns of some specific injury problems including poisoning,[5,6] aspiration,[7,8] falls,[2] drowning,[9] electrical shocks,[10] scalds and burns,[11] and injuries associated with playgrounds[12] and firearms.[13,14] Only a few studies have examined injury in US day care settings.[15–21] In the most comprehensive report to date, Sacks, *et al.*[15] found that 58 percent of all day care center injuries result from falls. Falls from playground equipment account for 48 percent of serious injuries, with the playground surface an important determinant of injury severity.

Despite the large numbers of children in organized child care, the incidence of childhood injury, and several legislative efforts, no federal day care regulations exist except for centers on military bases (70,000 children) and for Head Start programs (489,000 children).[16,17] Instead, each state formulates and enforces its own regulations. State day care regulations address many issues including disease transmission, hygiene, provision of nutritious and safe foods, provision of an environment which facilitates the child's mental, physical, and emotional growth, as well as injury prevention.

Our goal was to assess the content of state safety regulations and document how they are established and enforced.

Methods

The study consisted of three elements: 1) development of the set of model criteria to assess the regulations; 2) content analysis of the regulations; and 3) a questionnaire documenting day care regulatory processes in the states.

The reference criteria were drawn from three sets of nationally recognized guidelines: Massachusetts' Department of Public Health, *Safe Daycare: A Teacher's Guide for Creating Safe Environments for Preschool Children*[10]; American Academy of Pediatrics (AAP) *Health in Daycare: A Manual for Health Professionals*[24]; National Academy of Early Childhood Programs, *Accreditation Criteria and Procedures*.[23] From a combined list of 130 injury-related criteria, 36 specific items were selected by a panel of four injury specialists including three of the authors plus one independent reviewer. Selections were based on individual judgments of the panelists about the potential importance of the injury problem for young children but with an aim of including a diverse, if limited, set of categories. We specifically focused on regulations addressing environmental features of the facilities and center procedures rather than issues such as staff hiring and training practices or staff:child

ratios because the relationship between staffing patterns and injury potential is less well documented.

Content Analysis

The content analysis consisted of a comparison of each state's regulations to the 36 items. Each was rated as: 1) exceeding the criterion; 2) meeting the criterion; 3) being below the criterion; 4) not mentioning the content area; or 5) referring to other state regulations not specific to day care and not available to us (e.g. state building or fire codes). In the context of this study, we refer to day care as defined by the American Academy of Pediatrics[24] as "care, supervision, and guidance of a child or children, unaccompanied by parent or other legal custodian, on a regular basis, for periods of less than 24 hours." The content analysis, however, was restricted to analysis of regulations pertinent to day care center facilities. We excluded consideration of regulations specific to family day care as defined by the AAP; that is, "situations in which fewer than six children are cared for in the caregiver's home."[24] None of the criteria chosen delineated differences for specific age groups, although several of the criteria referred to issues specific to an age group (e.g. regulations about cribs).

Questionnaire

The questionnaire about the regulatory process and compliance was sent to the state agency responsible for regulating child day care at the same time the regulations were requested, by letter, from each state. The 15-item self-administered survey addressed the development and monitoring of safety regulations. Nonrespondents were phoned five weeks after the initial mailing and reminded of the survey.

Results

Analysis of Regulation Content

Regulations were obtained from 45 states and examined in comparison to the 36 criteria. Evaluations of the regulations, grouped by category, are presented in Table 1, demonstrating the proportion of states by whether each regulation exceeds, meets, or is below the criterion or if the topic is referred to in another code or not mentioned.

There were only five of the criteria (13.9 percent) that at least half the states met whereas 15 of the 36 items (41.7 percent) were not mentioned by half or more of the states.

For certain topics such as fire prevention, the state regulations frequently did not list specific requirements but referred to building codes or other state policies. Consequently, comparison to the criteria was impossible. For four of the six standards addressing fire and burn prevention, over half the states referred to other documents. At least 10 percent of the states referred to other regulations for swimming and wading pools, elevated areas, right hand descending stair railings, and motor vehicle passenger restraint.

Surprisingly, no state specified maximum heights for playground equipment, 96 percent neglected to mention playground surfacing, and 91 percent did not specify an eight-foot clearance between playground equipment.

There also were gaps in addressing indoor hazards. For example, 62 percent of the states were below the criterion in their restriction of objects that might cause choking, and no state specifically mentioned the most common causes of choking: hot dogs, peanuts, and grapes.[6,7] Only 26 percent of the states met the criterion for proper storage of poisonous substances, and a mere 11 percent specified that facilities not allow loaded firearms.

Although 55 percent of the states met or exceeded the criterion for tap water temperature, 38 percent failed to mention the issue. Eighty percent failed to meet the criterion that no free-standing space heaters be used.

Although 82 percent of states required that facilities have a first aid kit at the center at all times, only 18 percent required that at least one staff member be certified in cardiopulmonary resuscitation (CPR).

Subsequent to this analysis, the American Public Health Association (APHA) and the American Academy of Pediatrics (AAP) have drafted joint standards for child day care policy, including safety.[26] All of the 36 items included in our analysis are included in the AAP/APHA guidelines. For three of the 36 items, the AAP/APHA recommendations were more stringent than those used in this analysis, while for six others the AAP/APHA recommendations were slightly less stringent. For example, our analysis included a criterion that poisonous substances and medicines be kept in locked storage; the corresponding AAP/APHA guidelines indicated that there be "inaccessibility" of these substances.

The standards for Head Start programs were last revised in 1975 and indicate that if facilities meet or exceed state or local licensing requirements for fire, health, and safety this will "be accepted as prima facie compliance."[27] Our review of the 17 Head Start standards pertaining to safety indicated that none was more rigorous than the 36 criteria we considered.

Analysis of Perspectives on the Regulatory Process

Survey responses were received from 47 states (missing are Florida, Louisiana, and Maryland). Only four states *required* that injury prevention specialists be involved in developing regulations, although 16 states reported that injury prevention specialists are "routinely involved."

Safety regulation compliance by child day care centers was perceived to be good, with ratings of "better than average" reported by respondents from 26 states (55 percent). In contrast, compliance on the part of family day care homes was perceived to be "better than average" in 16 states (34 percent).

Respondents in 23 states indicated that at least one center had been closed in the prior year for safety violations and 19 reported that at least one family day care home had been closed. The types and number of inspections conducted by states varied widely. Types of inspections conducted included fire, gas pipe, sanitation, licensing, and routing monitoring; number of inspections per facility per year ranged from zero to six. Twenty-four respondents indicated that child day care centers in their states were inspected, on average, one or fewer times per year (e.g. every other year).

Those responsible for inspecting the facilities vary by state, with the jurisdiction for inspection shared by seven different types of groups or agencies. In some states, several different agencies were indicated as being responsible for development and/or enforcement of the regulations. In addition, respondents suggested that improvements were needed in: training for licensing and enforcement personnel; transportation policies; and attention to pets, electrical hazards, lead paint, and playground surfacing.

Discussion

Several limitations in the research should be noted. The content analysis was restricted to 36 specific day care center standards and to the 45 states providing

TABLE 1—Proportion of States by Level of Adherence to Criteria (n = 45)*

Criteria	Level of Adherence				
	Exceeds Criterion	Meets Criterion	Below Criterion	Topic not Mentioned	Refers to Other Code
Outdoor Hazards					
Wading pools emptied when not in use	2.2	24.4	11.1	44.5	17.8
All pools should be fenced & gates locked	6.7	20.0	17.8	24.4	31.1
Fences, natural barriers around play areas near busy streets, unsafe areas	0.0	73.3	6.7	20.0	0.0
Play equipment anchored, anchors below ground, no exposed concrete	0.0	6.6	35.6	57.8	0.0
At least 8 feet between all playground equipment	0.0	0.0	8.8	91.2	0.0
Maximum height of playground equipment 6 feet	0.0	0.0	0.0	100.0	0.0
8 inches or more of a resilient surface under playground equipment	0.0	0.0	33.3	66.7	0.0
Continuous maintenance of loose play surface materials	0.0	2.2	2.2	95.6	0.0
Flexible, light-weight, non-cutting swing seats	0.0	4.4	0.0	95.6	0.0
Structure of Facility					
Window openings limited to six inches	0.0	4.4	4.4	91.2	0.0
Elevated areas (landings, balconies, porches) provided with railings, adaptations, or approved safety gates	0.0	37.8	13.3	35.6	13.3
Right hand descending railing secured at child height	2.2	0.0	37.8	48.9	11.1
Above ground windows accessible to children must be constructed, adjusted, or adapted with window stops, screens, or grills	0.0	20.0	31.1	46.7	2.2
Indoor Hazards					
Non-metallic, tight-fitting caps in electric receptacles that are not in service in areas where young children are in care	0.0	55.5	0.0	44.5	0.0
Crib sides always up, in locked position when occupied	0.0	4.4	6.7	88.9	0.0
Toys, furnishings and equipment should be non-toxic, lead-free	0.0	48.9	33.3	17.8	0.0
Toys, furnishings and equipment should be free of rust, splinters and sharp corners	0.0	64.5	22.2	13.3	0.0
Toys, furnishings and equipment should be free from objects small enough to swallow	2.2	35.6	4.4	57.8	0.0
No peanuts, chunks of hot dogs, grapes	0.0	0.0	0.0	100.0	0.0
All potentially poisonous or hazardous substances kept in locked storage space, inaccessible to children	0.0	24.5	62.2	13.3	0.0
Rx/Non Rx medications kept in a designated locked place, inaccessible to children	0.0	28.9	60.0	8.9	2.2
No loaded gun permitted in child care facility	8.9	2.2	8.9	80.0	0.0
Fire/Burn Prevention					
Fire/Smoke Detector provided	2.2	37.8	2.2	0.0	57.8
Fire/Smoke Detector tested monthly (weekly)	2.2	6.7	2.2	17.8	71.1
Fire extinguishers provided	0.0	42.3	4.4	2.2	51.1
Fire extinguishers tested monthly (not specified)	0.0	4.4	15.6	15.6	64.4
Free standing space heaters should not be used	0.0	20.0	17.8	60.0	2.2
Hot water temperature should not exceed 120 degrees F at outlet	22.2	33.3	6.7	37.8	0.0
Emergency Procedures					
First Aid Kit in center at all times, wherever, whenever children are in care	0.0	82.2	8.9	8.9	0.0
At least one staff person on premises who is currently certified in CPR	2.2	15.6	8.9	73.3	0.0
Supervision					
Adult supervision of children at all times	0.0	91.1	8.9	0.0	0.0
No infant left unattended while bathing	0.0	11.1	0.0	88.9	0.0
Safety Education					
Safety education for parents	0.0	0.0	0.0	100.0	0.0
Safety education for children	0.0	4.4	2.2	93.4	0.0
Transportation					
All vehicle passengers seated in seats with suitable restraint system	0.0	22.2	31.1	26.7	20.0

*Data from the following jurisdictions were either not received or were not usable: Florida, Kansas, Louisiana, Maryland, Nevada and Washington, D.C.

documents. A separate analysis is needed to address the standards for the large population in family day care homes. The survey also was limited in several ways: only one representative responded from each state, and the role of these respondents may differ among states; anonymity was impossible, potentially reducing candor; and judgments of compliance were based on respondents' recall of "usual" practices which may vary widely. In addition, the scarcity of epidemiologic data about injuries occurring in day care facilities necessitates inferring, to a certain extent, that injury risks are similar to those documented for the total population of children under age five.

Nevertheless, the study does suggest the need for attention to a number of issues associated with the content, development, and monitoring of safety regulations for child care. The analysis revealed some important gaps in the regulations including inattention to playground design, firearms, and choking hazards. Given that playgrounds are the site of most reported injuries in day care centers, this oversight is especially noteworthy. Furthermore, six of the 36 standards studied were mentioned as covered under regulations other than those specific to day care by at least 20 percent of the states. It is impossible, in the context of this analysis, to assess the adequacy of those other regulations. References to other codes or standards, particularly those pertaining to fire and burn prevention, may be overlooked or misunderstood depending upon the communication and coordination among regulatory bodies or the extent to which the regulations are well-publicized. For example, knowledge about vehicle restraint laws may be more common than fire safety codes. In other instances, the failure to address an issue (e.g. firearms) may be based on the presumption that the issue is covered by other laws, a presumption that may or may not be true.

The deficiencies in the regulations reflect an inadequate regulatory process. As has been demonstrated with child automobile restraint policies, the lack of federal regulations results in diverse and inadequate state laws.[28] In the states, jurisdiction for day care safety is diffuse, with little input from injury prevention specialists. Furthermore, the relationship between regulations and the licensing process is variable among the states. Many of the regulations cannot be assessed until after a facility opens (e.g. supervision practices). Consequently, the role of inspection and relicensure may have more significance than initial licensing procedures and could benefit from further study. Interestingly, none of the national guidelines used as the basis of this analysis addressed the issue of inspection processes; however, the AAP/APHA guidelines[26] do include recommendations about inspections.

With large numbers of children in out-of-home-care other than day care centers, specific consideration of safety in family day care homes is essential. This requires attention to the delicate balance between access to affordable care on the one hand and, on the other, to the different hazards such as firearms that may be more prevalent in the home environment.

In the absence of a federal commitment, safety in child day care will remain dependent upon state actions. These efforts may be facilitated by the performance standards produced by the American Academy of Pediatrics and the American Public Health Association.[26] However helpful, they should not substitute for carefully constructed policy initiatives, preferably at the federal level, based on sound injury research. ☐

Women Who Are Most at Risk for AIDS Perceive It Least, Say Loyola Researchers

Two Loyola University Chicago researchers have found that women who are most at risk for HIV are the least likely to perceive themselves as being at risk. They also discovered that women who are at a high risk are no more likely to be tested than those who are at a low risk.

Although other researchers had long suspected both of these facts, the Loyola team was the first to document it.

Of the 320 women surveyed, an almost equal number of minority and nonminority women indicated that they engaged in high-risk behavior. However, significantly fewer high-risk minority women agreed with statements such as "I am concerned that I will get AIDS" and "I am concerned that someone I know will get AIDS" than did high-risk nonminority women.

The research was performed last winter by Seth Kalichman, PhD, assistant professor of psychology at Loyola, and doctoral student Tricia Hunter.

"The message about the methods of AIDS transmittal clearly does not seem to be reaching high-risk minority women," said Kalichman. "Surprisingly, most of the women we surveyed had seen mass transit ads on AIDS prevention. We're hypothesizing that the ads may be lacking in cultural relevance since they did not get the desired response."

To gather information about women's perceived risk for AIDS, Kalichman and Hunter chose a unique and highly effective location. The pair approached local women of assorted ages, races, and socioeconomic classes at various public transportation sites in downtown Chicago and asked them to fill out anonymous surveys on AIDS.

"We had a cooperation rate of 93%," said Kalichman. "We didn't know what sort of reaction we would get, and the response exceeded all of our expectiations."

The Loyola researchers gave participants who completed the survey a flyer that explained the purpose of the project, gave their university telephone number for more information, and, most importantly, according to Kalichman, provided the correct answers to the survey.

Along with the debriefing sheet, the researchers handed out cards from the Chicago Board of Health which explained where the women could go to have AIDS testing done.

Kalichman and Hunter attribute a large part of their success to the fact that they approached the women during nonrush hour periods when they were simply waiting for public transportation to arrive. But more than once, women passed up a ride to finish the Loyola-funded survey—proof, the researchers think, of the women's own interest in the subject.

Because so many men asked to participate in the survey (which was restricted to women only), Loyola hopes to follow up with a second survey which will collect information about men's perceived AIDS risk.

Promoting Physical Activity and a Healthful Diet among Children: Results of a School-Based Intervention Study

Bruce G. Simons-Morton, EdD, MPH, Guy S. Parcel, PhD, Tom Baranowski, PhD, Ronald Forthofer, PhD, Nancy M. O'Hara, PhD

ABSTRACT

Background: National health objectives call for improved diet and more regular physical activity among children. We tested the effects of a school-based program to improve students' diet and physical activity behavior at school.

Methods: Two of the four elementary schools in one Texas school district were assigned to intervention and two to control conditions. The three intervention components were classroom health education, vigorous physical education, and lower fat, lower sodium school lunches. Nutrients from school lunches and the total day and the amount of physical activity students obtained during physical education were assessed as outcome.

Results: Analysis of school lunches showed declines from base line to posttest in the two intervention schools of 15.5% and 10.4% for total fat, 31.7% and 18.8% for saturated fat, and 40.2% and 53.6% for sodium; posttest values were lower in the intervention schools. Observation of physical activity during physical education classes indicated an increase in the intervention schools from baseline to posttest in the percent of time children engaged in moderate-to-vigorous physical activity from less than 10% of class time at baseline to about 40% of class time at posttest; posttest values were higher in the intervention schools than in the control schools.

Conclusions: This efficacy study demonstrates the feasibility of substantially modifying school lunches and school physical education to improve children's diet and physical activity behavior at school. (*Am J Public Health.* 1991;81:986–991)

Introduction

Childhood diet and physical activity may lead to increased risk for cardiovascular disease (CVD) in adulthood.[1] Promoting a healthful diet and regular vigorous physical activity among children is a national public health objective.[2] School is an ideal setting in which to promote healthful diet and physical activity because these topics usually are part of the health education curriculum, and federally supported food services and state-mandated physical education (PE) are widespread.[3] School food services provide nutritious meals for 73.4% of all US public school students,[4,5] but the high fat and sodium content is a concern.[6] An estimated 97% of first- through fourth-grade children in US public schools are enrolled in school PE programs for an average of 100 minutes per week.[7] However, the frequency and duration of PE classes and the amount of moderate to vigorous physical activity (MVPA) children obtain during PE may be less than recommended.[8,9]

This study was designed to influence the school environment in terms of affect on student diet and physical activity at school. The Go For Health (GFH) program included a behaviorally-based health education curriculum, fitness-oriented PE, and lower fat and sodium school lunches. We report the effects of the program on children's dietary intake and physical activity during school.

Methods

Design and Study Population

The Texas City Independent School District (TCISD) was selected for the study because it is conveniently close to the university, it has an ethnic mix of students, and it has curriculum, school lunch, and PE components. The district participated in the US Department of Agriculture school lunch program, and each school had its own on-premises kitchen, cafeteria, and food preparation staff. Third and fourth graders had PE daily, taught by PE specialists. Facilities at each school include a modern gymnasium and large outdoor playground area. The population of students was 62.3% Anglo-American, 20.9% Mexican-American, and 14.8% Afro-American. The ethnic distributions were comparable for both treatment and control conditions.

Two of the four elementary schools (kindergarten through fourth grade) were assigned to intervention and two to control conditions. Third and fourth graders were assessed annually during three spring data collection periods.

Intervention

The three GFH intervention components, based on social cognitive theory,[10] were the Go For Health Curriculum, Children's Active Physical Education (CAPE), and the New School Lunch (NSL).[11] Following the model of Charter

[a] Baseline for control schools imputed from the average of the intervention schools.

and Jones,[12] we employed a four-step approach to program implementation and institutionalization.[13] To foster quality implementation, the GFH staff provided ample training, consultation, and technical support to both teachers and food service staff.

The purposes of the classroom health education, which consisted of six, behaviorally based modules, were to teach knowledge and skills essential to lifelong performance of the target diet and physical activity behaviors and foster the transfer of learning about these behaviors from school to out-of-school environments.[10]

The NSL was designed to provide lower-fat, lower-sodium lunches within the context of the existing school lunch program. Food purchasing, menus, recipes, and food preparation practices were modified.

CAPE, which consisted of five, 6- to 8-week units, was designed to encourage enjoyable MVPA among children during PE classes. Each unit included two or three main cardiovascular fitness activities, such as dancing, running, aerobic games, jump rope, and obstacle courses. Each class session consisted of warmup, fitness development, cool down, and skill development or game activities.

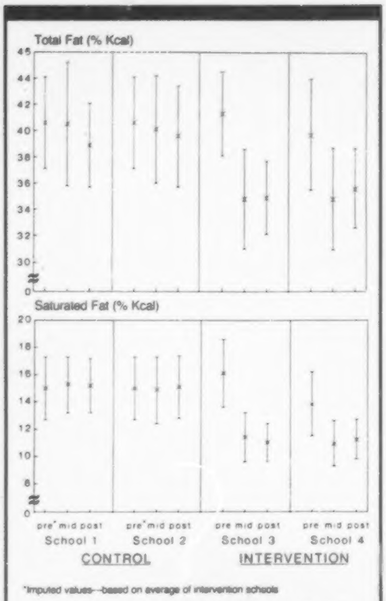

FIGURE 1—Means and 95% Confidence Intervals for Total Fat and Saturated Fat as a Percent of Calories in School Lunches (N = 12 meals per school) in Control and Intervention Schools at Baseline (Pre), after 1 Year (Mid), and after 2 Years (Post).

Measures and Procedures

Program effects were assessed by analyzing the nutrient contents of lunches, conducting 24-hour dietary recalls, and observing students' physical activity during PE.

Nutrient Analysis of School Lunches. The identical menu was repeated in March and April each year of the study. At baseline, 12 meals were selected randomly from the March and April menus and analyzed for nutrient content. Recipe analyses, based on detailed interviews with each cook in the intervention schools at baseline and in all four schools at midtest and posttest, were conducted by trained staff nutritionists and analyzed by the Nutrition Coding Center (NCC).[14]

Diet Recall. The 24-hour dietary recall interview was administered at posttest to random, cross-sectional subsamples of children, stratified by study school. Interviewers were trained according to NCC procedures and followed the NCC protocol for diet interviews. Each child was interviewed at home in the company of one parent, who was asked about ingredients, food preparation, and other items as needed.

Physical Activity. The time (in minutes) of MVPA performed by children during physical education was assessed by trained observers using the Children's Physical Activity Observation Form (CPAOF).[15] Study schools were observed on randomly selected days over a 2-month period each spring; all third- and fourth-grade classes were observed. Observers recorded on a minute-by-minute basis the type (e.g., basketball, jump rope) and intensity of physical activity. The CPAOF intensity categories have been validated against heart rate,[15] and the average heart rate for MVPA was 172.2 (SD = 21.2) beats per minute. Interobserver agreement was 97.0% (n = 57 paired observations).

Analysis

For energy and selected nutrients of potential concern in this age group, we calculated the means and 95% confidence intervals (CIs) of the repeated samples of school lunches in each school. For each separate treatment condition, we calculated the mean nutrient intakes from the 24-hour dietary interviews for selected nutrients and examined the contribution of school and bag lunches to total daily nutrient intakes.

For each school at each reporting period, we calculated the MVPA means, standard deviations, medians, and 95% CIs for the medians.[16] The median is the most appropriate statistic for purposes of comparing treatment effects because increases in the amount of MVPA on the part of only a few students could affect the mean value, obscuring true program effects. Percent of class time is preferable to minutes as an outcome because the scheduled length of PE classes varied somewhat from year to year, and the effective class time available for PE teachers and students, although similar in each school for a given year, varied somewhat from school to school due to local scheduling. The annual surveys are presented separately for each grade because most of one year's third graders became the next year's fourth graders; hence the data for each grade are not independent across years.

Results

Diet

Recipe Analysis. Table 1 includes the means and the 95% CIs for total energy (in kilocalories [1 kcal = 4.2 kJ]) and six nutrients in the 12 meals served in each study school each year. Baseline values for the control schools, which were not collected directly, were estimated by averaging the values of the two intervention schools. Declines from baseline to posttest in each school for protein, carbohydrates, total fat, cholesterol, and calcium are the product of declines in energy. The decline in calories served in the intervention schools appears to have been due mainly to a reduction in the amount of fat and carbohydrates. Despite the declines in energy, vitamin A and calcium did not decline, and posttest values for all schools exceeded the USDA school lunch requirements for each nutrient. For example, at every reporting the average intake of energy in each school exceeded 33% of the total daily requirement for energy, which is 600 to 700 kcal per meal.[17]

Shown in Figure 1 for each school is the average total fat and saturated fat as a percent of kcal served in the sample of 12 lunches. For both intervention schools the upper CIs of the posttest means were less than the pretest means, and in school 3 the upper and lower CI values did not overlap. The mean percent fat declined in school 3 by 15.5%, from 41.3% to 35.6% of calories, and in school 4 by 10.3%, from 39.7% to 35.6% of calories. Average percent saturated fat declined in school 3 by 31.7%, from 16.1% to 11.0% of calories, and in school 4 by 18.8%, from 13.8% to 11.0% of calories. The means for percent total fat and saturated fat at posttest in the control school were within the imputed pretest 95% CIs.

Figure 2 shows that the sodium content in the school food declined from baseline to posttest in school 3 by 53.6% from 2141.1 mg to 993.0 mg, and in school 4 by 40.2%, from 1730.0 mg to 1034.5 mg. These differences remained after controlling for kcals served. Sodium in the control schools did not decline from the imputed baseline value.

Dietary Recall. Table 2 shows the analysis of the posttest 24-hour recalls for the nutrients of interest. Students in the intervention group, compared with students in the control group, reported fewer calories (2094 vs 2135 [1 calorie = 4.2 J]) and less total fat (77 g vs 90 g), saturated fat (29 g vs 34 g), and sodium (2873 mg vs 3378 mg) for the total day. In comparison with control group students, intervention group students reported consuming less total fat, saturated fat, and sodium in both tray and bag lunches.

Physical Activity

Table 3 shows medians, means, and standard deviations for minutes of MVPA for observed students in grades three and four at each study school at baseline, midtest, and posttest. At baseline, mean MVPA for third and fourth graders was less than 3 minutes at each school; medians were 2.0 minutes or lower. At posttest, mean minutes had increased in school 3 to 11.7 (third grade) and 15.0 (fourth grade) and in school 4 to 16.2 (third grade) and 16.1 (fourth grade) per class.

Median minutes as a percent of class time and 95% CIs around the medians are shown for third and fourth grade in Figure 3. For both grades, the median percent of class time in MVPA at baseline was zero in three schools and less than 10% in school 3. At posttest, the control school medians were still no greater than 5% of class time. In the intervention schools, however, the posttest medians were substantially higher, 28% of class time for third graders in school 3, and 39% of class time or greater for the other intervention groups. Except for fourth grade in school 3, the upper and lower 95% CI values do not overlap with the baseline means.

Discussion

The results show strong positive program effects on children's diet and physical activity at school. At posttest, school lunches in the intervention schools provided less energy, fat, and sodium compared with baseline and with the control schools, while adequate levels of other essential nutrients were maintained. Similarly, children's physical activity in the intervention schools was much higher at posttest than at baseline and in comparison with the control schools.

Several studies have demonstrated that sodium reductions can be accomplished by intervention directed at school meals.[18,19] However, no studies have reported systematic reductions in fat and sodium in school lunches. In the GFH intervention schools, sodium content was reduced to target levels, saturated fat reductions of 31.7% and 18.8% occurred, and posttest values approached the target goal of 10% of kcals served. Total fat reductions were modest, 15.5% and 10.3%, and the target goal of 30% of kcals was not reached, indicating that it is easier, even in institutional settings, to substitute fat type than to reduce the amount of fat.

The 24-hour dietary recall data indicate that the changes in nutrients served in

school lunch contributed to improvements in total daily dietary intake of calories, total fat, saturated fat, and sodium. Children did not make up in other meals for reductions of fat and sodium in school lunches. Energy, calcium, and vitamin A remained adequate at posttest in all schools, suggesting that reductions in fat can be accomplished without undue reductions in other essential nutrients.

Several studies have demonstrated that it is possible to modify PE to improve cardiorespiratory fitness.[20-22] Our results indicate that it is possible to increase time devoted to MVPA from less than 10% to more than 40% of available class time. At posttest, the typical student in the intervention schools obtained about 16 minutes of MVPA per daily PE period, or 80 minutes of MVPA per week. It must be noted that these modest results were obtained after 2 years of intervention that involved one staff person virtually full time in the provision of intensive training of PE teachers. Because PE accounts for nearly half of children's total daily physical activity,[23] the extremely low level of MVPA observed in all schools at baseline is a cause for concern, particularly if future research determines that low levels of activity during PE are prevalent in American schools.

This is the first US study to demonstrate the potential of altering the school environment to promote a more healthful diet and more vigorous physical activity among children, although at least one successful European study has been reported.[24] Strengths of the present study include planned implementation of theory-based individual and organizational interventions, two intervention and two control schools within the same district, and objective measures of diet and physical activity. Limitations of the study include the lack of baseline recipe data for the control schools, nonrandom assignment of schools to treatment conditions, and the small number of study schools.

The results of this efficacy study suggest that school is a potentially important site for improving children's diet and physical activity and that such changes are possible. In our experience, however, schools do not change readily, and substantial staff training should accompany policy changes regarding healthful school lunch and vigorous physical education. Before widespread implementation of these changes occurs, effectiveness studies with larger numbers of schools are needed to determine the ability to generalize these approaches and to assess cost effectiveness. ☐

Acknowledgments

This research was funded by NHLBI Grant 33376. We gratefully acknowledge the administrators, teachers, and staff of the Texas City Independent School District for their support and cooperation. Also, we thank Renee Fleishman for data preparation and Iris Huang for statistical analyses.

This research was presented at the annual meeting of the American Public Health Association held in New York City September 30 to October 4, 1990.

National Primary Care Nurse Practitioner Symposium Issuing Call for Abstracts

The 17th National Primary Care Nurse Practitioner Symposium is accepting abstracts of research, innovative clinical practice/models and roles, and other professional papers relating to primary care nursing. Abstracts are being accepted for presentation (plenary) or poster sessions. This symposium, sponsored by the University of Colorado Health Sciences Center School of Nursing, will be held July/early August, 1992, in a Colorado mountain resort.

Please send three typed copies (300 words or fewer), limited to one page, single spaced, with 1-1/4 inch margins. Abstracts must be photocopy-ready and include title. A separate page with author contact information may be used. Format includes title, brief statement of purpose, methods, conclusions, and clinical application(s) or, if not a research abstract, brief summary of project/paper. Include author vita and indicate interest in presentation (plenary) and/or poster session.

Preference will be given to abstracts with strong clinical applicability, innovative role development models and papers with future-oriented perspective.

Presenters are provided tuition waiver for registration the day of their presentation, but are responsible for their own travel and expenses. Deadline is October 14, 1991.

Contact Ellen Lemberg, RN,C, MS, Nurse Practitioner Symposium Office, School of Nursing, University of Colorado Health Sciences Center, 4200 East 9th Avenue, Box C287, Denver, Colorado 80262. Tel: 303/270-7436.

Attitudes toward Abortion among Parents of Children with Cystic Fibrosis

Dorothy C. Wertz, PhD, Janet M. Rosenfield, MS, Sally R. Janes, MSW, and Richard W. Erbe, MD

ABSTRACT

Background: DNA prenatal diagnosis for cyctic fibrosis (CF) has been available for parents of affected children since late 1985.

Methods: Using anonymous questionnaires, we surveyed 395 parents of children with CF at 12 New England CF centers with regard to 12 maternal or family situations and 11 fetal characteristics; 271 (68%) responded.

Results: The majority supported legal abortion in the first trimester for all 23 situations; 58% would abort for severe mental retardation (MR), 40% would abort for a genetic disorder leading to death before age five years, 41% for a child bedridden for life, 35% for moderate MR, 20% for CF and 17% for a severe incurable disorder starting at age 40 years. Few would abort for a disorder starting at age 60 years, for genetic susceptibility to alcoholism or for sex selection. Variables most strongly related to abortion for CF were attitudes of spouse, respondent's siblings, and CF doctor toward abortion for CF as well as infrequent attendance at religious services.

Conclusions: Prenatal diagnosis may not reduce substantially the number of CF births to parents of CF children because most do not accept abortion for CF. (*Am J Public Health.* 1991;81:992–996)

Introduction

Parents of children with genetic disorders are frequently ambivalent toward selective abortion of affected fetuses and may regard the abortion as a rejection of their affected child. Although some studies report that the majority of these parents do not consider abortion acceptable for the disorder in question,[1–8] other studies indicate that such parents may be more willing to abort than the general population.[9–10]

Attitudes toward abortion follow a spectrum of perceived severity, severe mental retardation (MR) being the most crucial factor. Most women (94% to 97%) with prenatally diagnosed fetal abnormalities involving severe MR (e.g., trisomies 13, 18, or 21) choose abortion.[11] Fewer women (62%) choose abortion for sex chromosome abnormalities (e.g., 45, X Turner syndrome or 47, XXY Klinefelter syndrome) that are not ordinarily associated with retardation.[12] Severe physical disability ranks next. Among women undergoing MSAFP (maternal serum α-fetoprotein) screening for neural tube defects, 57% would abort if there "was a very good chance that the child would be born with a serious physical handicap [sic], for example, blindness or paralyzed legs."[13]

Some common genetic disorders such as cystic fibrosis (CF) involve neither MR nor significant physical limitations, but carry a reduced life expectancy and increased morbidity. CF is the most common autosomal recessive disorder affecting Caucasian populations, with an incidence of 1 in 2000 to 3000 births. About 30 000 individuals in the United States are affected. Improved palliative treatment has extended life expectancy and improved quality of life. In 1988, 75% survived into their late teens, half reached the age of 26, and about 40% reached the age of 30, though few survived to their fifth decade.[14]

Since late 1985, identification of deoxyribonucleic acid (DNA) probes linked to the CF gene has allowed accurate prenatal diagnosis for families who have had a previous child with CF and for whom specimens for the affected child and both parents can be analyzed in parallel with amniotic fluid or chorionic villi (CVS) specimens.[15–16] In other nations the majority of such families (65% in Belgium,[17] 52% in Wales[18]) would abort a CF fetus. In France, parents chose to terminate 53 of 56 CF fetuses following prenatal diagnosis.[19] There are no comparable studies in the United States. Our specific aims were (1) to find out how parents of affected children viewed abortion for CF, and (2) to see where parents placed CF in a wider spectrum of situations that might justify abortion.

Methods

Questionnaire Content

Our questions on abortion were part of a larger study of psychosocial factors

This paper was submitted to the journal October 2, 1990, and accepted with revisions April 4, 1991.

affecting use of prenatal diagnosis for CF in six New England states. We anticipated that parents might be less likely to abort for CF than for severe MR, severe physical disability, conditions that threatened the mother's life or health, and rape or incest, and more willing to abort for CF than for late-onset or cosmetic conditions.

We asked about attitudes toward abortion in 23 situations, including 12 maternal or family situations and 11 conditions affecting the child. Respondents were asked to give one of three responses: (1) "I would have an abortion," (2) "I would not have an abortion, but it should not be prohibited for others," or (3) "I think abortion should be prohibited by law." We included situations described in opinion polls (mother's life, rape, incest), or used as rationales for abortion (maternal age under 15, mother's career, financial burden, family completed). In describing fetal characteristics, we avoided listing names of specific disorders and instead briefly described the child's condition (e.g., instead of trisomy 18, "severe mental retardation: child unable to speak or understand"; instead of Tay-Sachs, "severe genetic disorder leading to death before age 5"; instead of Huntington disease, "severe painful disorder starting at age 40, incurable"). We included several conditions that are not presently diagnosable prenatally, such as susceptibility to alcoholism, "severe incurable disorder at age 60" (Alzheimer disease), and "severe, untreatable obesity." We included obesity because of concerns that, if ever given the opportunity, some parents may make prenatal selections on cosmetic grounds, such as hair, eye, or skin color, or stature.[20] Finally, we included sex selection because, despite much publicity and two recent surveys of physicians,[21-23] there are no surveys of parental attitudes.

Previous studies have found associations between abortion attitudes and religion,[9,10,24] religiosity,[13,25] education,[10,25,26] income,[10] previous elective abortion,[9] and interpretation of risk,[9] but a recent study of CF families in the United Kingdom found no association between abortion attitudes and social class.[18] The 15-page questionnaire included the above variables and sections on reproductive history, reproductive plans, health of the affected child, expectations about the child's activities 5 and 10 years from now, knowledge about new genetic tests, and standard sociodemographic data. Most questions called for categorical (yes-no) responses. Five-point Likert scales were used to describe the interpretation of risk and the attitudes of spouses, members of extended family, and medical professionals toward abortion for CF, and (in a separate question) support of those persons carrying a CF fetus to term.

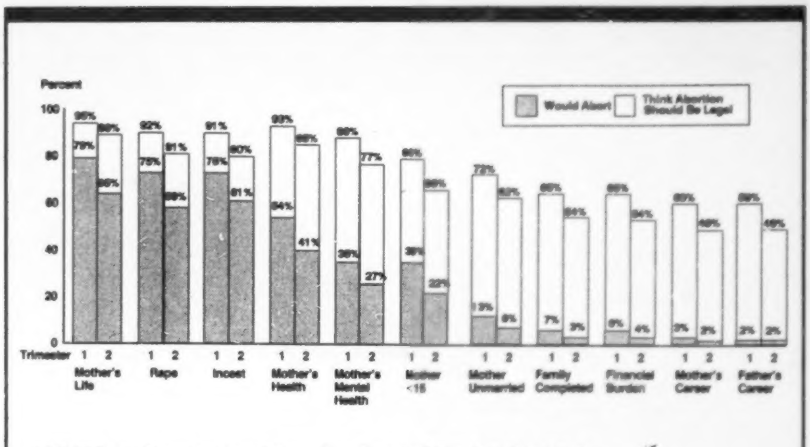

FIGURE 1—Abortion for Maternal or Family Situation (N = 271).

There are liabilities in studying attitudes rather than actual behaviors. Low prevalence and the practical difficulties of obtaining abortion histories limited us to a study of attitudes. Some studies have found attitudes strongly related to subsequent behavior.[24,27]

Distribution

Starting in January 1989, all 12 CF centers in New England distributed the questionnaires to parents of children enrolled as patients. Depending on the clinic, questionnaires were either given out at regular clinic visits over a 4-month period (most CF patients visit every 3 months) to be returned by mail, or were mailed directly to families. The two modes of administration produced almost identical response rates. In order to ensure anonymity, all questionnaires were returned directly to project staff at the Shriver Center, not to the clinics.

Data Analysis

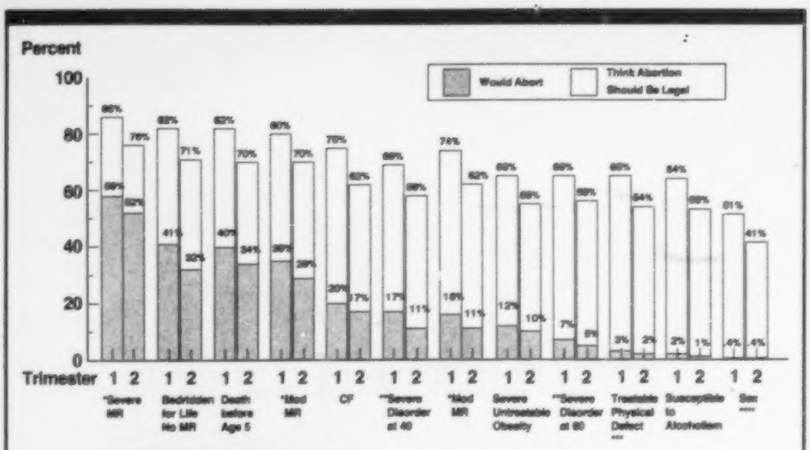
Questionnaire data were entered into Statistical Package for the Social Sciences (SPSSX) and Statistical Analysis System (SAS) programs. Using the statement "I would have an abortion" in the first trimester as the dependent variable, we looked for associations with sociodemographic variables, child's health, future expectations, interpretation of risk, and extended family's attitudes toward abortion. The five-point Likert scales were reduced to three points in order to eliminate small cells for "strongly approve." Analyses of subsets by gender, religion, and religiosity (weekly attendance) were conducted to rule out the possibility of interaction.

For each of the 23 abortion questions, all variables that associated, at the zero-order level, with "I would have an abortion" were entered into a stepwise logistic regression. This method orders each independent variable in terms of its strength of association with the dependent variable, while controlling for other variables. For each independent variable that was significantly associated, the method provided an odds ratio for personal acceptance of abortion.

Profile of Respondents

Of 395 parents asked to participate, 271 (68%, 228 families) responded. Their children's health status corresponded generally with the national clinical profile of CF.[11,28-29] The children's median age was seven; 90% had pancreatic involvement; 73% required chest physical therapy, including 46% who required it from one to five times daily; and 42% had been hospitalized within the last year.

Parents appeared typical of CF families in other studies: median age was 35; 36% were college graduates and median income was $30 000 to $40 000. These figures were comparable to an earlier California study of CF families' attitudes toward prenatal diagnosis.[30] Seventy-eight percent were living with the affected child's other parent, and 57% were Catholic, figures comparable to a New York City study.[31] The high proportion of Catholics may result from greater frequencies of the CF gene in the Irish, Italian, and French populations found in New England.[14,31] Of respondents, 73% were fe-



*Severe MR: Unable to speak or understand

FIGURE 2—Abortion for Fetal Characteristics (N = 271).

male and 13% had had a previous elective abortion. In all, 52% had been surgically sterilized (compared with 62% in a previous study[30]), 15% were either beyond reproductive age or no longer living with the child's other parent, and 33% were still fertile and at risk for having another child with CF.

Although 27 persons did not respond to the question about abortion for CF in the first trimester or to other questions about abortion, there were no statistically significant differences between respondents and nonrespondents.

Results

Responses are described in Figure 1 (maternal or family situations) and Figure 2 (fetal characteristics). The majority believed that abortion should be legal in all 23 situations during the first trimester and in 20 of the 23 situations during the second trimester (white bars). For all situations, fewer respondents approved legal abortion in the second trimester than in the first trimester, with an average difference of 11 percentage points.

There was a steady gradation in personal acceptance of abortion (shaded bars), running from "mother's life in danger" down to "child would interfere with father's career" (Figure 1) and from "severe mental retardation" to "child is not of sex desired by parents" (Figure 2). Severe MR was the only fetal characteristic for which the majority (58%) would themselves abort (Figure 2). For CF itself, 20% would abort in the first trimester, and 17% in the second trimester.

In both Figures 1 and 2, 80% to 100% of those represented in a shaded bar are also represented in the shaded bars to the left. For example, of those who would abort for CF, 86% would also abort for moderate MR, 88% if the child would be bedridden for life, and 100% if the child would die before age five or have severe MR. An average of 9% fewer women would abort in the second trimester than in the first trimester for maternal or family situations, and an average of 5% fewer women would abort in the second trimester for fetal characteristics. Men made less differentiation between trimesters (6% for maternal situations and 1% for fetal characteristics).

Characteristics associated at the zero-order level with personal willingness to abort are presented in Table 1. Men were more likely than women to say either that they would abort or that abortion should be prohibited by law. Men eschewed the middle ground of not aborting but permitting it for others. Gender was not related to any responses concerning fetal characteristics.

For all maternal or family situations and all fetal characteristics except sex selection, attitudes toward abortion were associated with respondent's perception of attitudes of spouse, mother, father, and siblings toward abortion of a fetus with CF. The majority thought that their spouses (65%), mothers (60%), fathers (55%), and siblings (51%) would disapprove. These views were closely interrelated, with Pearson correlation coefficients of >.6. Family attitudes toward abortion for other disorders were not surveyed.

In addition, the following variables (not reported in Table 1) were associated with abortion for CF: perceived approval of abortion for CF by father-in-law or mother-in-law, approval of abortion for CF by affected child or by other children, approval of abortion for CF by CF doctor or genetic counselor, and perceived absence of support from spouse, family doctor, or CF doctor for carrying a fetus with CF to term.

Not associated with any attitudes toward abortion, including abortion for CF, were age, fertility status, marital status, number of children, CF child's health, future expectations about the CF child, cost of the child's illness, knowledge about prenatal diagnosis, interpretation of genetic risk, and reproductive intentions. No sociodemographic variables were significantly related to abortion for obesity, severe disorder at 60, susceptibility to alcoholism, treatable defect, or sex selection.

Stepwise logistic regression analyses were performed for all abortion situations in Table 1. Characteristics strongly and independently related to willingness to abort ($P < .10$) are indicated.

Some general patterns emerged from the regression analyses. Religious background was related largely to maternal or family situations, where traditional Catholic social values may remain, rather than to abortion for fetal characteristics. In many situations, those with higher education were more willing to abort than those with less education.

Family attitudes were among the strongest factors related to personal abortion decisions. For persons living in a family context, it is difficult to make an abortion decision that contradicts the values of their spouses and extended families. Respondents' perceptions of their mothers' views were especially important for maternal or family situations. For spousal views, respondents' perceptions were accurate in the 43 families in which both spouses responded.

Regression results for abortion for CF and severe MR are reported in Tables 2 and 3. Table 2 shows that parents' perceptions of the views of their CF doctors toward abortion for CF were significant. In all, 15% thought their CF doctors would approve, 45% thought they would disapprove, and 40% thought they would be neutral.

TABLE 1—Psychosocial Characteristics Associated with Personal Willingness to Abort in Selected Situations (N = 271)

	Abortion Situation														
Psychosocial Characteristic	Mother's life	Rape	Mother's health	Mother's mental health	Mother under 15	Mother unmarried	Family completed	Financial burden	Severe MR	Bedridden for life	Death before 5	CF	Moderate MR	Mild MR	Severe disorder at 40

Variable	Beta	P	Odds Ratio[a]
Siblings approve abortion for CF (3-point scale)	1.0319	.05	7.88
Spouse approves abortion for CF (3-point scale)	0.9396	.002	6.55
Infrequent attendance at religious services (4-point scale: once a year to weekly)	0.5791	.002	5.68
Spouse would not support carrying a CF fetus to term (3-point scale)	0.7713	.004	4.68
CF doctor approves abortion for CF (3-point scale)	0.3105	.06	1.86

[a] Odds that a respondent at one end of the variable scale will abort, when compared with a respondent at the other end.
Note: n = 222.

Discussion

The major finding, that a minority of parents of children with CF (20%) would abort a CF fetus, suggests that prenatal diagnosis will not lead to a substantial reduction in the number of CF births among this group, at least in the United States. Most parents in this sample apparently do not regard selective abortion for CF as an acceptable reproductive option, although they believe this option should be available to others. Many affected families may not welcome public health efforts to provide prenatal testing for CF.

The majority of CF families may proceed as they did before prenatal diagnosis became available: they will either curtail reproduction (as many do) or take their chances. However, in the wider spectrum of abortion attitudes, the majority would abort for severe MR and many for a child bedridden for life. Optimism about CF was pervasive; families expected their child to reach age 40, hold a full-time job, and marry. With discovery of the gene for CF, optimism has probably increased.

At the other end of the spectrum, few would abort for adult-onset disorders starting at age 40 or 60, for genetic susceptibility to alcoholism, or for sex selection, areas now receiving much attention. Although overall responses suggest that most would not use abortion frivolously, responses to the obesity question aroused our concern. Apparently, there is a not insubstantial minority who would abort for cosmetic purposes if prenatal assessment were possible.

The trimester of pregnancy had less relationship to personal willingness to abort than might be expected. For most fetal conditions, including CF, only 5% fewer women would abort in the second trimester than in the first. This result suggests that newer methods of prenatal diagnosis, such as CVS, which make first-trimester abortions possible, may have little effect on deeply held attitudes.

In genetic counseling, it would be appropriate to acknowledge the effects of extended family networks on patients' views and to encourage patients to discuss the relationship between personal and family values. The attitude of the physician caring for the affected child may influence parents' decisions. Few believed that their CF doctors would support abortion of a fetus with CF. Counselors should discuss these parental perceptions, which may reflect the clinically necessary optimism conveyed by pediatricians, rather than the doctors' actual views. Finally, the relationships between sociodemographic var-

Infant Diet and Salmonellosis

Robert L. Haddock, DVM, MPH, Simon N Cousens, MA, DipMathStat, and Catherine C. Guzman, MPH, RD

ABSTRACT

Background: **The Island of Guam has experienced a high incidence of infant salmonellosis for a number of years (age-specific incidence rate of approximately 3700 cases per 100 000 infants in 1984). Interviews of case parents suggested that the use of high-iron infant formula was associated with this problem.**

Methods: **A case-control study was conducted to test this hypothesis. Information on feeding practices and a variety of medical and socioeconomic factors was collected for 78 laboratory-confirmed *Salmonella*-case infants and 167 control infants.**

Results: **Case infants were less likely to have been breast-fed (odds ratio [OR] = 9.15; 95% confidence interval [CI] = 2.71–30.9) and more likely to have been fed infant formula with an iron content of 10 mg/L or greater (OR=2.96; 95% CI = 1.24–7.08) than were control infants.**

Conclusions: **Although the precise means by which infants are most commonly exposed to *Salmonella* bacteria remain obscure, breast-feeding apparently protects against the development of physician-diagnosed clinical salmonellosis, while the feeding of high-iron infant formula has the opposite effect. (*Am J Public Health.* 1991;81:997–1000)**

Introduction

The incidence of nontyphoid salmonellosis on the island of Guam increased from 78.6 cases per 100 000 population in 1975 to a peak of 218 cases per 100 000 in 1984. The incidence has declined to 110 per 100 000 in 1989, still more than 5 times the US rate for the same year.[1] Infants typically account for about 50% of *Salmonella* cases on Guam. Another unusual characteristic of the epidemic is the presence of *S. waycross,* a serotype that is rare elsewhere in the world but accounts for about 30% of all human *Salmonella* isolates on Guam. In 1984, only 3 of 35 862 cases of salmonellosis reported in the United States were due to *S. waycross;*[2] all three cases were residents of Guam who were referred to the state of Hawaii for medical treatment (A. P. Liang, personal communication, 1987).

Several investigations have failed to link infant cases of this epidemic to the consumption of foods with an animal origin (including milk), to secondary spread from infected family members, or to the ownership of pets or domestic animals.[3-5] Infant salmonellosis cases occur with approximately equal frequency in both civilian and military communities as well as in families of both higher and lower economic status.[3] Investigations of infant day care and formula preparation practices have not provided any clues to the origin of infant salmonellosis cases.[4]

During the course of an earlier unpublished study of this problem, we were impressed by an apparent association between infant salmonellosis cases and a history of being fed iron-supplemented brands of infant formula. Samples of these products, obtained both from case households and unopened from grocery shelves, were invariably sterile, however.

In 1984 an article in the veterinary literature reported that weanling pigs administered therapeutic amounts of iron orally developed more severe *Escherichia coli* diarrhea than pigs to which the same amounts of iron were administered by intramuscular injection; the authors theorized that increased amounts of available iron in the intestinal tract promoted the multiplication of otherwise harmless numbers of potentially pathogenic bacteria, thus rendering them better able to cause overt disease.[9]

Since iron-enriched formula is commonly fed to infants, we initiated a study to determine if the iron content of formula could be contributing to the problem of infant salmonellosis on Guam.

Methods

A case-control study was carried out using as cases, infants born on Guam who developed laboratory-confirmed salmonellosis before their first birthday. Cases were identified prospectively as laboratory reports were received from the Guam public health reference laboratory. (All medical laboratories on Guam, including

TABLE 1—Crude odds ratios (OR) for Iron Content of Formula Fed at Onset of Illness in Non-Breast-Fed Cases of Infant Salmonellosis and Non-Breast-Fed Age-Matched Controls

Formula	Cases	Controls	OR*	95% CI
Low-iron	13 (17.3%)	37 (30.0%)	1.00	
High-iron	62 (82.7%)	88 (70.0%)	2.96	1.24–7.08

*OR and 95% CI estimated retaining age-matching.

military facilities, routinely submit isolates of *Salmonella, Shigella,* and *Vibrio* to this laboratory for confirmation and serotyping.)

Controls were identified by selecting the next two births listed in the Guam birth registry following the case-birth registration, thereby matching for age and season of birth. If an infant selected as a control was deceased, or a salmonellosis case, or had previously been selected as a control, the next registered birth was selected. If a selected infant had been treated by a physician for diarrhea or if efforts to locate parents were not successful, the next birth certificate was selected, and the process was repeated until two controls had been enrolled in the study.

Parents of case infants were asked what milk their infant was being fed when the diarrhea developed, and parents of control infants were asked what milk their infant was being fed at the same age. Formula brands were assigned to one of two categories: low iron (less than 10 mg/L) or high iron (10 mg/L or more). Upon completion of each interview, data on the age, ethnicity, education, and marital status of the parents, infant birthweight and APGAR score, complications of pregnancy or delivery, month of pregnancy during which prenatal care began, number of prenatal physician visits, and number of previous births to the mother were excerpted from birth certificates.

Names of all study infants, without identification as to whether they were cases or controls, were submitted to the Special Supplemental Food Program for Women, Infants and Children (WIC) staff to determine if they had [illegible] enrolled in that program.

Statistical Methods

Cross-tabulations and simple statistical tests, including χ^2 tests, were performed using the computer package PC-SAS.[10] Odds ratios (OR) and their 95% confidence limits (CI) were estimated by conditional logistic regression analysis, retaining the matching of controls to cases as suggested by Breslow and Day,[11] using the computer package EGRET.[12]

Results

Of 96 cases of salmonellosis reported in children less than 1 year of age during this study, 18 (18.8%) could not be traced. In selecting controls, birth certificates of 389 infants were examined. Of these, 131 (34%) were excluded from the study for various reasons, 112 being untraceable. Of the remaining 258 controls, 167 had no history of treatment by a physician for diarrhea and were enrolled in the study.

Cases were less likely to be receiving breast milk at the time they developed salmonellosis than their age-matched controls (3.9% vs 25.2%), suggesting that failure to breast-feed infants on Guam is associated with an approximately ninefold increase in the risk of symptomatic salmonellosis infection (OR = 9.15, CI = 2.71–30.9). This association remained after taking into account potentially confounding variables.

To compare infants with regard to the iron content of infant formula received, those infants receiving breast milk were excluded, leaving a total of 75 cases and 125 controls. Cases were more likely than controls to be receiving infant formula with a high iron content (OR = 2.96, CI = 1.24–7.08; Table 1). Ninety-six percent of cases enrolled in the WIC program received a high-iron formula compared with 75% of cases not enrolled. Among controls, 80% of infants in the WIC program received a high-iron formula compared with 67% of those not in the program. No association between education of parents or marital status of mother and type of infant formula used was observed.

Each of the variables included in Table 2 was then considered individually as a potential confounder of the association between type of infant formula and risk for salmonellosis using the technique of conditional logistic regression. Controlling WIC enrollment led to the greatest reduction in the estimate of the odds ratio (OR = 2.54, CI = 1.02–6.28), while controlling marital status led to the greatest increase (OR = 3.85, CI = 1.51–9.84). A conditional logistic regression model including the variables listed in Table 2 was then fitted. Problems of collinearity prevented the simultaneous inclusion in the model of terms for father's ethnic group and age. All other variables were included. When father's ethnic group was omitted from the model, the estimated OR of the association between high-iron infant formulas and salmonellosis was 4.74 (CI = 1.28–17.57). Excluding father's age from the model produced an OR estimate of 4.04 (CI = 1.09–14.94).

Discussion

It has been suspected for some time that infants born on Guam may be infected with *Salmonella* bacteria by some means other than the more commonly recognized modes of transmission. The discovery that both indoor and outdoor environments on Guam were heavily contaminated with *Salmonella* bacteria[13,14] and that the incidence of infant salmonellosis in particular was linked to seasonal changes in environmental conditions[15] seemed to support the hypothesis that infant salmonellosis might frequently be a consequence of contamination of the infant's environment rather than the result of consuming contaminated food products or contact with infected family members.[16] It was also suspected that the immunologic naivete of newborn infants was a key factor in facilitating infection by the relatively small number of *Salmonella* bacteria that were likely to be encountered in an apparently clean home environment and that were harmless to other family members. The results of this study suggest that absence of breast-feeding and high levels of iron in some brands of infant formula may also be factors that contribute to an increased risk for infants' developing clinical salmonellosis on Guam.

Reported complications associated with pregnancy or delivery was the only other variable to show a substantially elevated OR in our univariate analysis (Table 2). This trend remained in both multivariate models (OR = 2.79, CI = 0.76–10.26, father's ethnic group excluded, and OR = 3.68, CI = 1.08–12.55, father's age excluded). Complications reported in more than one case included wrapping of umbilical cord around neck of infant (14), meconium staining of infant (8), Caesarean delivery (6), and premature rupture of membranes (2). These infants may have been at increased risk of being identified as salmonellosis cases because of decreased resistance to infection or because they received more intensive medical attention following delivery. While we did not measure either disease-specific or general infant immunity levels, our analysis did use the number of antenatal physician visits as a proxy measure of the tendency of parents to utilize medical services.

Other possible biases in this study include loss of 18 (18.9%) cases and 11 (28.8%) controls. Factors that contributed to the high rate of unlocateable cases and controls included the mobility of younger families, the concurrent use of as many as three different house-numbering schemes in some areas, and the frequent absence of addresses or telephone numbers in patient records. The fact that case address information obtained from health care providers was more current than control address information listed on birth certificates may have affected the success rates for locating individuals from these two groups.

Of initially selected controls, 91 were excluded from the analysis because they had a history of physician treatment for diarrhea and might therefore have been unidentified cases of salmonellosis. Trial inclusion of these children in the analysis led to some reduction in the final estimate of the OR of the association between type of infant formula and risk of salmonellosis, as might be expected if misclassification of disease status had occurred (OR = 2.34, CI = 1.22–9.16), but would not materially alter our interpretation of the results.

A biased estimate of the OR might also have arisen through failure to control other confounding variables. While socioeconomic status has not been controlled directly in the analysis, maternal and paternal education, both indicators of socioeconomic status, have been controlled. Enrollment in the WIC program, which is restricted to low-income families, has also been controlled. Cost differential between low- and high-iron formulas is not a factor, as both formulations cost the same.

Weaning practices could also be a confounding factor, but since 60% of children in the study were age 3 months or less, it seems unlikely that this could have played a substantial role in the observed associations. Formula preparation practice was not examined because an earlier investigation suggested that this was not a risk factor for infant salmonellosis on Guam.[4]

Note: OR and 95% CI estimated retaining age-matching.

It has previously been reported that breast-feeding and available dietary or serum iron can influence the course of infections.[17–22] Since mother's milk contains only about 1.5 mg of iron per liter and normal full-term infants exclusively breast-fed for 4 to 6 months by mothers in normal health are unlikely to develop iron deficiency,[23] it may be that maintaining a relatively low concentration of iron in the neonatal gastrointestinal tract is one of nature's strategies for protecting infants from bacterial infections during the critical first few months of life. Commercial iron-supplemented infant formula, on the other hand, contains from 12 to 19 mg of iron per liter and would provide the intestinal flora of infants fed these products with from 8 to 12 times more iron than is available to breast-fed infants.

Although one of the objectives of the Guam WIC program is to encourage breast-feeding, this study found that breast-feeding was less common among WIC program participants than among nonparticipants (19% vs 28% among controls). The enticement of offering free infant formula to new mothers may be more effective in determining actual nursing practice than present educational efforts designed to foster knowledge and attitudes favorable to breast-feeding. Current regulations of the WIC program stipulate that infant formula containing less than 10 mg of iron per liter may be provided only when a physician determines that the recipient infant has an existing medical condition that contraindicates the use of iron-supplemented formula. This study suggests that such a requirement may contribute to the problem of infant salmonellosis on Guam.

For the 10-year period 1981 to 1990, the average annual age-specific incidence rate for infant salmonellosis on Guam peaked at age 2 months (approximately 4580 cases per 100 000) but fell by more than 50% by age 6 months (approximately 2140 cases per 100 000). This result suggests that it would be advisable to breast-feed Guam newborns for at least 6 months and to delay feeding iron-supplemented infant formula for the same period when breast-feeding is not possible.

While we have only studied the relationship between salmonellosis and infant diet, it is possible that other bacterial diseases are similarly affected. It has already been demonstrated using an animal model that oral iron supplementation can cause an exacerbation of diarrhea due to *E. coli* infection,[9] and both pathogenic strains of *E. coli* and *Campylobacter* (a bacteria similar epidemiologically to *Salmonella*) are known to be important causes of childhood diarrhea in many countries.[24–26]

Although a relatively high nonresponse rate among both cases and controls and the other potential sources of bias outlined in this report suggest that a cautious interpretation of our conclusions is warranted, we believe that the data presented here, together with a biologically plausible mechanism previously reported, warrant further investigation. Certainly any inexpensive and readily implemented strategies that have the potential to significantly affect the important worldwide problem of infant diarrheal disease merit serious consideration. □

Controlled Trial of *Giardia lamblia:* Control Strategies in Day Care Centers

Alfred V. Bartlett, MD, Steven J. Englender, MD, MPH, Betty A. Jarvis, RN, Lois Ludwig, RN, John F. Carlson, and James P. Topping

ABSTRACT

Background: Strategies for control of *Giardia lamblia* in day care differ in numbers of children treated and in costs to parents and day care operators. The effectiveness of these strategies has not been systematically evaluated.

Methods: We conducted a prospective randomized controlled trial comparing three strategies for control of *Giardia* in infant-toddler day care centers: Group 1, exclusion and treatment of symptomatic and asymptomatic infected children; Group 2, exclusion and treatment of symptomatic infection only; Group 3, exclusion and treatment of symptomatic infection, treatment of asymptomatic infection in the center. The study included 31 day care centers with 4180 child-months of observation. *Giardia* prevalence was determined before intervention and 1, 2, 4, and 6 months later; new infants and toddlers were tested on admission.

Results: Initial *Giardia* prevalences were 18% to 22% in the three groups. *Giardia* was identified in 10.5% of 676 new infants and toddlers entering study day care centers during the 6-month follow-up. *Giardia* prevelances by intervention group were 8%, 12%, and 7% at 1 month, and 7%, 8%, and 8% at 6 months.

Conclusions: The stricter intervention resulted in greater cost in terms of child day care and parents' work days lost, but did not result in significantly better control of *Giardia* infections in this day care environment. (*Am J Public Health.* 1991;81:1001–1006)

Introduction

Giardia lamblia infection and diarrhea have been increasingly identified in association with child day care centers, especially those caring for infants and toddlers: day care center outbreaks have been reported from Atlanta, Tucson, Houston, and Phoenix, with 17–54 percent of children in these outbreaks found to be infected.[1–4] A prospective study in Phoenix, Arizona day care centers found *Giardia* to be the most frequently identified enteric pathogen in diarrhea outbreaks and in sporadic diarrhea among infants and toddlers.[4]

Asymptomatic children in day care centers where *Giardia* diarrhea is identified are also frequently infected.[1,2,5] These asymptomatic infections are of theoretical concern in developing disease control strategies because asymptomatic carriers often excrete the infective cyst form of the parasite.[5,6] However, the actual relation of such asymptomatic excretion to *Giardia* transmission in day care centers has not been documented.

For almost 10 years, the Maricopa County (Greater Phoenix) Department of Health Services had utilized a very strict intervention strategy to control giardiasis in centers where the parasite was identified by passive laboratory-based surveillance and case investigation:

- If the case is a day care center child or worker, all children and staff were tested for *Giardia*.
- All symptomatic and asymptomatic *Giardia*-infected children and adults were excluded from the center, with recommendation for treatment.
- Excluded children or staff were readmitted to the center when treatment was completed and two *Giardia*-negative stool examinations had been documented.
- The center was given advice regarding hygienic practices to reduce transmission of enteric microorganisms.

Although this strategy had substantial impact on families and centers involved, its effectiveness in *Giardia* control had not been evaluated. We therefore conducted a controlled study of the effectiveness of this strategy in comparison with other strategies for control of *Giardia lamblia* infection among infants and toddlers in Phoenix day care centers.

Methods

General

This was a prospective randomized (unblinded) controlled trial. All centers having a case of *Giardia lamblia* infection identified in an infant (age 0–11 months) or toddler (age 12–35 months) during the period October 1986–September 1987 were considered for inclusion in the study. Permission of the director and parents was required for participation. On acceptance of participation, each center was assigned to one of the three control strategies, using prenumbered sealed envelopes containing the group assignment derived from a table of random numbers according to a block randomization scheme. If a center de-

clined participation, *Giardia* control was managed according to the existing policy and excluded from study and analysis. This study was approved by the Committee on Human Subjects of the Maricopa County Department of Health Services.

Control Strategies (Intervention Groups)

Group 1. Exclusion and recommendation of treatment for symptomatic and asymptomatic infections; readmission after completion of treatment, and two *Giardia*-negative stool examinations by the health department (existing strategy).

Group 2. Exclusion and recommendation of treatment for symptomatic infections only; readmission when asymptomatic, with continued treatment and follow-up testing in the center. No exclusion or treatment of asymptomatic infections.

Group 3. Exclusion and recommendation of treatment for symptomatic infections; readmission when asymptomatic, with continued treatment and follow-up testing in the center. Treatment and follow-up testing of asymptomatic infections in the center, without exclusion.

All groups received the same standard orientation regarding hygiene practices to reduce spread of *Giardia*.

Outcome Variables

Effectiveness of the intervention strategies was assessed by comparing prevalences of *Giardia* among infants and toddlers at 1, 2, 4, and 6 months after intervention, and occurrence of *Giardia*-positive diarrhea among infants and toddlers during intervals between follow-up prevalence test rounds.

Data Collection

Information on each participating center included total enrollment, number of infants (if present) and toddlers, type of organization, operating hours, child group mixing, staff supervising more than one child group, and location within Phoenix (zip code sector). Standardized observations regarding sanitary and child care practices were made by study nurses during the six-month follow-up period in each center. Information on each participating child was obtained at the time of center entry into the study for children enrolled at that time (original enrollees), or on entry to the center for children enrolling during the six-month follow-up period (new enrollees). These data included age, sex, ethnic group, attendance status (regular, drop-in), duration of enrollment (original enrollees) or previous day care (new enrollees), other concurrent day care, parent occupation, household size, presence of siblings by age group, home location (zip code sector), pets, exposure to untreated water (by type), and travel history. Information subject to short-term change was re-ascertained by interview at the time of follow-up test rounds.

Giardia lamblia *Prevalence Testing*

Consistent with existing procedures, *Giardia* infection was determined by examination of a single stool specimen collected by the center or parents and tested in the health department laboratory. Prevalence testing at each specified interval was conducted during a period of two weeks. A minimum testing compliance standard (at least 75 percent of enrolled infants and toddlers) was maintained for all test rounds and, when necessary, the test period was extended until this testing level was obtained. In almost all follow-up prevalence testing rounds this level was exceeded, and the mean proportion of enrolled children tested in follow-up test rounds was 83 percent.

New entry children were initially tested within two weeks of admission. In subsequent test rounds, children enrolling after intervention were retested along with original enrollees. Results of initial *Giardia* tests of original enrollees were known to study nurses, center staff, and parents. Study and center personnel and parents were blinded to results of new enrollee testing and of follow-up test rounds for all children.

Surveillance for Diarrhea

Nurse field workers made daily telephone calls to each study center to identify cases of diarrhea (stools looser and more frequent than normal for that child) among infants and toddlers, and to obtain attendance figures. Visits to each center were made at least weekly to deliver specimen collection materials, reinforce study methods, and verify enrollment. When diarrhea occurred in a study child between follow-up test rounds, a stool specimen was collected for *Giardia* testing. Test results of children with diarrhea were known to study personnel; if *Giardia*-positive, children with diarrhea were managed according to the control strategy for their center.

Parasitologic Methods

Fresh stool specimens were immediately placed in two vials, one containing polyvinyl alcohol (PVA) and the other 10 percent formalin, by the parent or center worker. All specimens were examined by ethyl-acetate-formalin concentration of the formalin-preserved stool, followed by staining with D'Antoni's modified iodine and direct microscopic examination at 100× and 400× magnification. Specimens from children with diarrhea were also examined for *Giardia* trophozoites using trichrome staining of the PVA-preserved stools. For quality control, a subset of specimens was randomly selected and also tested using an indirect immunofluorescent assay for the detection of *Giardia* cysts in feces (Merifluor-*Giardia*, Meridian Diagnostics, Cincinnati, Ohio).

Potential Confounding Variables

Variables which might affect the rate of *Giardia* infection among the children and centers in the different intervention groups were identified from review of pertinent literature. We performed two analyses to assess the association of these variables with *Giardia* infection among Phoenix infants and toddlers, and to examine additional local variables (such as geographic sector of the city or exposure to untreated water used for irrigation of some yards and public parks) which might be associated with infection. The first analysis was a case-control study comparing the 51 new enrollee children without previous day care attendance who were found to be *Giardia*-infected on admission to study centers (cases) with the 482 new enrollee children without previous day care who were not infected on admission (controls). A second analysis compared characteristics of 52 children age 0–35 months who had never attended day care and who were identified as *Giardia*-infected during the study period by health department surveillance, with 52 age-matched controls randomly selected from county birth records who also had never attended day care and who were confirmed as not infected by stool testing. The prevalences of confounding variables identified from the literature or by one of these analyses were then compared in the three intervention groups, to identify those which would need to be considered in analysis of the effect of intervention strategy on *Giardia* prevalence.

Association of center characteristics with prevalence of *Giardia* was examined by comparing the 14 study centers having initial *Giardia* prevalences above the mean for all study centers, with the 17 study centers having lower initial *Giardia* prevalences.

Statistical Analysis

Prevalences of *Giardia* among infants and toddlers in the centers in each of the three intervention groups at each of the specified test points were compared using ANOVA. Comparison of rates and proportions was performed using chi-square, Fisher's exact, and Wilcoxon-Mann-Whitney tests. To examine the effect of intervention group on *Giardia* prevalence, accounting for the effects of confounding variables, a nested ANOVA model was used.

In all of these analyses, the null hypothesis (that no significant association existed between an independent variable and the outcome under study) was rejected if the probability of chance association was <0.05.

Estimated Costs of Control Strategies

Our study was not designed to provide a detailed cost-effectiveness analysis of the various *Giardia* control strategies. However, we did attempt to estimate the costs of these strategies to the families actually participating in the study. Projections regarding the number of children requiring medical treatment, costs of these treatments, and number of day care and parent work days lost were developed for asymptomatic and symptomatic children under the different intervention strategies. These projections were then applied to the actual number of such children in each group at the time of intervention.

The projections assumed exclusion and treatment of all *Giardia*-positive children in accordance with the protocol for their treatment group. In Group 1, duration of exclusion of all *Giardia*-positive children was projected as two weeks or 10 day care days (10 days treatment, four days follow-up testing after treatment). In Groups 2 and 3, duration of exclusion of symptomatic *Giardia*-positive children was projected as one week (five day care days) until end of symptoms and readmission. To develop projections of treatment costs and parent work days lost we conducted a survey which included 38 percent of parents of study children who were *Giardia*-positive at the time of initial intervention.

TABLE 2—Prevalences of *Giardia Lamblia* on Initial and Post-intervention Testing among Infants and Toddlers in Study Day Care Centers, by Intervention Group and Enrollment Category

Intervention Group	Enrollment Category	Initial	1 month	2 months	4 months	6 months
1	Already enrolled*	20% (258)	7% (165)	7% (181)	8% (183)	6% (175)
	New**	—	10% (58)	11% (54)	9% (74)	9% (34)
	Total	20% (258)	8% (223)	8% (235)	8% (257)	7% (209)
2	Already enrolled*	18% (308)	12% (193)	14% (211)	12% (217)	6% (207)
	New**	—	12% (32)	6% (67)	8% (93)	15% (60)
	Total	18% (308)	12% (225)	12% (278)	10% (310)	8% (267)
3	Already enrolled*	22% (299)	6% (195)	10% (190)	8% (191)	7% (209)
	New**	—	12% (34)	13% (60)	10% (78)	14% (36)
	Total	22% (299)	7% (229)	11% (250)	8% (269)	8% (245)

*Already enrolled = Children enrolled at initial testing, or enrolled throughout the interval ending in each test round.

**New = Children enrolling during the interval ending in the test round.

During the one-year enrollment period, 35 centers with an index case of *Giardia lamblia* infection in the infant-toddler age group were identified. Of the 32 centers having additional cases of infant-toddler *Giardia* infection, all accepted participation; one center was dropped after intervention for failure to comply with the study protocol and its data were excluded from analysis. The remaining 31 centers completed six months of follow-up for a total 4,180 infant-toddler child-months of observation. Characteristics of these 31 centers are shown in Table 1, by intervention group.

Immediate Observations after Intervention

The overall prevalences of *Giardia* at the time of intervention did not differ significantly among the infants and toddlers in each of the intervention groups (20 percent in Group 1, 18 percent in Group 2, and 22 percent in Group 3). The ranges of *Giardia* prevalences in the individual centers at intervention were 6–32 percent in Group 1, 8–30 percent in Group 2, and 5–47 percent in Group 3.

Table 2 presents overall *Giardia* prevalences by intervention group among children already enrolled (prior to the intervention for initial testing and during the entire interval between tests for each subsequent test round) and for children newly enrolled during each of the intervals between test rounds. Several differences between intervention groups were noted in the first month after intervention. In Groups 1 and 3 there were significant reductions in overall *Giardia* prevalence at one month, to 8 percent and 7 percent, respectively. Although the overall prevalence in Group 2 also declined to 12 percent, the difference was less, consistent with the fact that this intervention did not treat asymptomatic *Giardia*-positive children.

In addition, all groups experienced drops in enrollment after initial identification of *Giardia* and intervention imple-

TABLE 3—Contribution of Original and New Enrollees to the Total Infant Toddler Study Population and to *Giardia Lamblia* Infection at Conclusion of Six Months' Follow-up, by Initial *Giardia* Test Result

Enrollment and Test Result Category	Proportion Six Months Post-Intervention Total Infants and Toddlers (n = 721) %	 Total *Giardia*-positive Infants and Toddlers (n = 56) %
Original Enrollees

Initially *Giardia*-negative	43	18
New Enrollees		
Initially *Giardia*-positive	4	39
Initially *Giardia*-negative	41	25

TABLE 4—Episodes of Diarrhea and *Giardia*-positive Diarrhea Occurring in Study Infants and Toddlers between Follow-up Test Rounds, by Intervention Group

Intervention Group	Child-months between Test Rounds	Total Number of Diarrhea Episodes	Number of *Giardia*-Positive Episodes (%)
1	832	60	6 (10)
2	1,048	183	29 (16)
3	907	81	16 (20)

mentation. There were significant differences among intervention groups in the proportion of initially *Giardia*-positive children who left study day care centers in the first month after intervention: only 7 percent of *Giardia*-positive children dropped out of Group 3, compared to 25 percent in Group 1 and 20 percent in Group 2. The drop-out rates of *Giardia*-negative children in the first month after intervention in the three groups were 15, 14, and 16 percents, respectively.

Finally, compliance with post-treatment testing was significantly reduced in the groups where such testing was not required prior to re-admission: only 71 percent of children treated in Groups 2 and 3 submitted one or more post-treatment clearance specimens. Compliance with treatment may also have been different: of treated children submitting post-treatment specimens, 23 percent in Groups 2 and 3 remained *Giardia*-positive, compared to 4 percent in Group 1.

Six-Month Follow-Up

Prevalence of Giardia lamblia. As shown in Table 2, Groups 1 and 3 had similar overall prevalences of *Giardia* at each of the follow-up test points. Although *Giardia* prevalences in Group 2 were somewhat higher than those in the other two groups at the 1, 2, and 4 month follow-ups, by the six-month follow-up the overall *Giardia* prevalences in the three groups were virtually identical (7, 8, and 8 percents, respectively).

Contribution of new versus original enrollees and initial test status to outcome. Table 3 shows the contribution of initially *Giardia*-infected and uninfected original and new enrollee children to the total study population and to *Giardia* infection at the end of follow-up. Six months after intervention, original enrollees accounted for 55 percent of infants and toddlers and for 36 percent of *Giardia* infection. Children who had been *Giardia*-infected at the time of intervention were over three times more likely to be infected six months later than children originally not infected. The importance of originally *Giardia*-positive children in total infection after six months was actually greatest in Group 1, despite these children having been subject to the strictest intervention and post-treatment testing.

Initial testing of all new infant-toddler enrollees found 10.5 percent to be *Giardia*-positive upon entering study centers; this proportion did not differ significantly among intervention groups (10 percent in Groups 1 and 2, 12 percent in Group 3). At six months after intervention, 57–75 percent of *Giardia*-positive infants and toddlers in each group were children who had enrolled after the intervention. New enrollees who were *Giardia*-positive on admission comprised only 4 percent of the total infant-toddler population at six months post-intervention, but accounted for 39 percent of all *Giardia*-infected children.

Giardia-associated diarrhea between test rounds. Table 4 shows the number of diarrhea episodes identified between test periods in each intervention group, and the proportion of these episodes which were *Giardia*-positive. The overall rates of diarrhea and of *Giardia*-positive diarrhea were significantly higher in Group 2 than in Groups 1 and 3. However, the proportions of diarrhea episodes which were *Giardia*-positive were not significantly different among the three groups. Increased testing in response to a greater number of episodes of diarrhea might have resulted in detection of more "*Giardia*-positive" diarrhea in Group 2. However, the testing and treatment of symptomatic *Giardia*-positive children represents an additional control measure which would have had more effect in Group 2 than in Group 1 or 3.

Potential confounding variables. Five characteristics other than day care attendance were found to be significantly associated with infant-toddler *Giardia* infection in new enrollees without previous day care who entered study day care centers, or in the case-control study of *Giardia*-infected 0–35 month old children not attending day care. Comparison of the prevalences of these characteristics among study children in the three intervention groups found very low prevalences of two (Native American ethnic group, 2–5 percent; well water exposure, 1–2 percent). Two other characteristics were more common, but were almost equally prevalent in all groups (household size ≥ 5 persons, 25–29 percent; presence of a 3–5 year old sibling, 28–32 percent). Only one factor, the study child belonging to the toddler (12–35 month) age group (versus the infant age group), was significantly associated with *Giardia* infection and differed significantly in its distribution between the three intervention groups (78 percent in Group 1, 65 percent in Group 2, and 82 percent in Group 3, $p < 0.01$.). The lower proportion of toddlers in Group 2 would be expected to lower the observed prevalences of *Giardia*, while the higher proportion of toddlers in Group 3 would be expected to raise the observed prevalences of *Giardia* in that group.

Among all new enrollees, previous day care center (but not day care home) attendance was significantly associated with *Giardia* infection, but only 8 percent of new enrollees had previously attended a day care center.

No day care center characteristic was significantly associated with higher prevalence of *Giardia* on initial testing, although this analysis was limited by the small total number of centers.

Multivariate analysis. To examine the effects of the *Giardia* control strategies taking into account the differences in age distribution among the day care centers in the three groups, we employed a series of nested ANOVA models which included *Giardia* prevalence (at one of the specified test points for each model), intervention group, proportion of infants and toddlers tested at that point who were in the toddler age group, and individual day care center (nested within intervention group). In these models, the differences in proportion of toddlers were significantly associated with differences in *Giardia* prevalence at the time of initial testing and at 1, 2, and 4 months after intervention. Intervention strategy was not significantly associated with differences in *Giardia* prevalence at any test point.

Estimated Costs of Control Strategies

Our survey of parents of *Giardia*-infected children at the time of intervention found the mean cost of physician visits associated with this diagnosis to be $34 (range $1–$120) and the mean cost of medication to be $12 (range $2–$60). Forty-two percent of these parents reported missing work in association with their child's exclusion from day care, with a projected mean of 6.6 days for parents in Group 1, and 3.5 days for parents in Groups 2 and 3.

Table 5 presents the projected estimates of costs which result from applying these results to each of the intervention groups at the time of intervention and throughout the six months of study including the intervention. These estimates are based on the actual number of symptomatic and asymptomatic children detected at the time of intervention, and on the additional cases of *Giardia*-positive diarrhea detected during follow-up. For the initial intervention, Group 2 had substantially lower projected costs than Group 1 in terms of both medical costs and of day care and parent work days lost. Group 3 had lost time costs similar to Group 2, but had substantially higher medical costs resulting from the treatment of asymptomatic as well as symptomatic children.

TABLE 5—Estimated Costs of *Giardia* Control Strategies in Study Day Care Centers at the Time of Initial Intervention and Total during Six Months of Observation, by Intervention Group

	Cost at Initial Intervention/Total Cost Over Six Months		
	Group 1	Group 2	Group 3
No. of children excluded	52/58	22/51	18/34
Medical treatments required	52/58	22/51	67/83
DCC days lost	20/580	110/255	90/170
Parent work days lost	114/161	32/75	26/50
Physician costs	$1,768/$1,972	$748/$1,734	$2,278/$2,822
Prescription costs	$624/$696	$264/$612	$804/$996

By the end of six months, the large number of cases of *Giardia*-positive diarrhea in Group 2 resulted in a total number of excluded children, and resulting projected medical costs, similar to those of Group 1. Because of the difference in exclusion requirements between Group 1 and the other two groups, the projected numbers of day care and work days lost remained substantially lower in Groups 2 and 3 throughout the period of study.

Discussion

Strategies for control of specific infectious diseases in child day care must be principally based on concern for the health of the infected or ill child, the probability of transmission of infection to other children or adults, the effect of infection on these other persons, and the preventive or curative control measures available. At the same time, these strategies must be developed and implemented taking into account their impact on the child, the family, employers, and day care providers. Physicians and local health authorities have usually had to develop disease control interventions in the absence of adequate information regarding their effectiveness and impact.[6–8]

Giardia lamblia has been recognized as a problem in day care of diaper age children, and *Giardia* infection has been associated with day care center attendance.[1,2,9,10] In Phoenix and in some other day care environments, asymptomatic *Giardia* infection among infants and toddlers in centers has also been documented to be prevalent.[4,5] These asymptomatic infected children present a special disease control dilemma, since limited data suggest no adverse nutritional impact of such infection among well-nourished immunocompetent children,[5] and no increase in diarrhea rate among such children compared with *Giardia*-negative children in the same settings.[4,5] However, these asymptomatic infected children do represent a potential source of infection to others.

The existence of a very strict health department strategy for control of *Giardia lamblia* in Maricopa County (greater Phoenix) day care centers gave us the opportunity to perform this randomized controlled evaluation of that strategy in comparison with two less strict strategies. Our study was designed as an effectiveness evaluation of these intervention strategies under existing conditions of day care centers, turnover of enrollment, and medical treatment provided by community care providers, rather than an efficacy evaluation in which these variables would be controlled by the investigators. For the same reason, we continued to identify day care centers having *Giardia*-infected infants and toddlers through the existing health department surveillance mechanism and continued the health department policy of identifying *Giardia* through a single stool examination.

Several immediate differences emerged between intervention groups. At one month after intervention, significant reductions in *Giardia* prevalences existed in the two groups of centers where both symptomatic and asymptomatic children were treated; a lesser non-significant reduction in prevalence occurred in the group of centers where only symptomatic children were treated. Part of this immediate reduction in *Giardia* prevalence was attributable to *Giardia*-positive children leaving the study centers. Although we did not investigate whether these *Giardia*-positive children moved to other day care centers and infected other children, molecular epidemiological study of *Shigella*-infected day care center children has identified such transfer of infection to other child groups in response to control measures.[11]

At the end of the six-month follow-up period, no control strategy was associated with significantly lower prevalences of *Giardia* among infants and toddlers in study centers, although the six-month prevalences in all three groups were significantly lower than the prevalences at the time of intervention. Of equal importance is the recognition that the 8 percent overall prevalence of *Giardia* at six months after intervention is essentially the same as the 10.5 percent prevalence of *Giardia* among the infants and toddlers who entered study centers during the follow-up period; the majority of these new enrollees had not previously attended a day care center. *Giardia*-positive new enrollees accounted for almost 40 percent of *Giardia* infection at six months. The unexpectedly high prevalence of *Giardia* among Phoenix infants and toddlers without previous day care histories, and the high turnover of children characteristic of this center population, suggests that *Giardia* control strategies for Phoenix day care centers cannot expect to reduce prevalence below this apparent background level.

These characteristics of the Phoenix population of infant-toddler center users probably limit the external validity of our findings to similar populations. It may be that in an infant-toddler population with very low prevalences of *Giardia* and low rates of center turnover, strict control strategies might result in elimination of *Giardia* from a given center. In the Phoenix day care center environment, however, our data indicate that the existing strategy did not achieve substantially greater control of *Giardia* infection, especially in comparison with the strategy that treated both symptomatic and asymptomatic infection with less stringent exclusion requirements.

Our data do not permit general recommendations regarding the need for *Giardia* testing of young children in day care who experience diarrhea. They do suggest that, in environments comparable to Maricopa County, *Giardia* testing should be considered if microbiological testing is indicated in an episode of diarrhea in an infant or toddler (whether in a day care center or not) or if a day care center is experiencing a diarrhea outbreak.

Our projected estimates of the cost of the different strategies were consistent with parents' and day care owners' experience that the existing strategy resulted in substantial numbers of child day care and parent work days lost. While initially the least costly, Group 2 experienced more diarrhea during follow-up, resulting in total medical costs comparable to the existing strategy.

Our data do not permit distinction of diarrhea caused by *Giardia* infection from diarrhea of other etiology occurring in a child who was coincidentally infected by *Giardia*. However, if the reduced initial costs of Group 2 were accomplished at the expense of additional preventable child illness, this would clearly be an unacceptable strategy. The greatest difference in projected costs between strategies, and that most important to parents and day care operators, resulted from the difference in exclusion requirements. The *Giardia* prevalence results and diarrhea experience in Group 3 suggest that these less stringent requirements did not result in an outcome substantially different from that of the stricter exclusion policy.

Although the cost of conducting controlled trials of public health disease control strategies restricts the usefulness of this approach, documentation to the extent possible of the effects and impact of these strategies can represent an important contribution to day care disease control efforts. Certainly, in various child day care environments additional information is needed on the control of *Giardia lamblia* and other infectious diseases important in preschool age children. ☐

Acknowledgments

The authors wish to express their appreciation to the parents, children, and staff of the day care centers who collaborated in this study, to the study nurses, and to H. Robert Baird, MS, for his support in data analysis. This work was supported by a grant from the Arizona Disease Control Research Commission. Presented in part at the 99th Annual Meeting of the Society for Pediatric Research, Washington DC, May 1989.

Characteristics of Maternal Employment during Pregnancy: Effects on Low Birthweight

ABSTRACT

Background: Although maternal employment is considered a risk factor for low birthweight (LBW), the manner in which employment might affect birthweight is poorly understood. In this analysis, selected charateristics of employment during pregnancy were examined for effects on pregnancy outcomes.

Methods: Work characteristics included the number of hours per week, physical activities, and environmental conditions. The outcomes of interest were fetal growth retardation (<2500 grams at term) and preterm delivery (<37 weeks). The study population consisted of 2711 non-Black, married mothers who participated in the 1980 National Natality Survey (NNS). The NNS data were merged with data from the 1977 revision of *The Dictionary of Occupational Titles* (DOT) from which measures of occupational physical activities and environmental exposures were obtained. Logistic regression was used in the analysis.

Results: Those who worked 40 or more hours per week were more likely than women who worked fewer hours to have a low birthweight delivery at ≥37 weeks. No physical or environmental characterics of work were associated with low birthweight or preterm delivery.

Conclusions. Non-Black married American women may face a risk of delivering low-birthweight babies at or near term only if they work 40 or more hours each week. However, the lack of risk associated with other characteristics of work may be a function of measurement error in the DOT data source or of low levels of exposure in the analysis population. Introduction

Infants weighing 2500 g or less at birth may be small for gestational age, the result of a preterm birth, or both.[1] The two low-birthweight (LBW) categories share many risk factors[2] but are caused by different physiological mechanisms.[3] For women who work during pregnancy, characteristics of employment have been associated inconsistently with both outcomes.

Studies in developing countries suggest that hard physical labor during pregnancy has adverse effects on fetal growth.[4–6] In industrialized nations, standing,[7–10] carrying or lifting heavy loads,[8,11] strenuous physical effort,[12–15] work on assembly lines[12] and industrial machines,[13] and some occupations that involve physical effort, such as chambermaid, janitor, and hospital worker,[8,16] have been associated with delayed fetal growth, preterm birth, or both. However, in other investigations, each of these findings has either not been supported[8,12,17–22] or has not been examined.

Studies of environmental conditions such as temperature, dust, and moisture have found few associations with either category of LBW.[8,17,23] However, one study found loud noises associated with lower birthweight,[8] while in another, an "environment" index was associated with preterm birth.[13]

Physical and environmental exposures at work may influence pregnancy by decreasing uterine blood flow,[24,25] by stimulating production of catecholamines[26,27] or both. Presumably, these processes can be accelerated or decelerated by amount of exposure. Hence, studies in which number of hours worked per day or week are taken into account are potentially informative. However, the studies that have included these variables have produced inconsistent results.[7,8,12,13,18,19,22,28]

Most of the research in this area has been done in Europe,[10–13,19,20,29] with some recent reports from Montreal.[8,16] Of the 10 American studies reported in the literature,[7,9,14,15,17–19,22,28,30] four found no significant effects of maternal employment.[17–19,28] Also, the analysis of the Collaborative Perinatal Project data of the early 1960s[7] may not be applicable to current working populations. Most of the US studies have focused on a few physical activities (notably that of standing) and on hours and duration of work to the exclusion of environmental exposures. Also, confidence in the findings of the studies of American women is tempered by measurement problems. In some cases, employment characteristics were assigned post hoc by the investigators or other experts to occupational titles.[7,9,17,18] Variations by individual or work site were not taken into account, and the validity of the coding schemes was unknown. Another approach was to collect employment data after the delivery,[19,22] when recall may

Editor's Note. See related editorial on p. 973.

have been clouded by elapsed time, the relative significance of the birth event, the health of the infant, or all of these factors. Homer et al.[14,30] avoided these sources of error by imputing employment characteristics from an independent data base. However, they may have introduced a new source of self-report bias because the data were collected by surveying workers.

The purpose of the present study was to examine the effects of selected physical and environmental characteristics of maternal employment and amount of work (hours/week) on fetal growth and preterm delivery in a representative sample of contemporary American women. To avoid the measurement error in assessment of job characteristics associated with self-report and expert opinion, data on employment characteristics were obtained from an independent source derived primarily from work-site observations.

Methods

Data Sources

This study is an analysis of the 1980 National Natality Survey (NNS), a follow-back survey of a probability sample of registered births in the United States. Approximately 1 in 400 live births ≥2500 g and 1 in 95 live births <2500 g are in the NNS sample, which totals 9941. Data were collected from birth certificates and requested by mail from hospitals and other health care providers. In addition, detailed sociodemographic and behavioral data as well as basic information on employment during the 12 months before the birth were requested by mail from mothers who were married at the time of delivery. The data collection process involved three mailings and an attempt to interview nonrespondents by telephone. Overall response was 79.5% from married mothers and 76.1% from hospitals. All data were collected retrospectively, within 1 year of the 1980 deliveries.[31,32]

The NNS data set was merged with the 1977 Dictionary of Occupational Titles (DOT), which includes descriptive data on more than 12 000 distinct occupations in more than 75 000 sites.[33] DOT data were collected by on-site interviews with workers and from observations of jobs as they were performed.[34] A detailed job analysis schedule[33] was completed for each job and, if feasible, verified by the worker's immediate supervisor.[34] One or two workers were observed for each job analysis. Scores on 44 work characteristics were then assigned by the analyst based on detailed guidelines and examples.[35]

Study Population

The study population consisted of 2711 non-Black (97% White) singleton live births to married mothers who worked during pregnancy and provided sufficient data on occupation and industry to match with DOT job characteristics. NNS subjects with imputed data entries on employment items, birthweight, or gestational age at delivery were not included in the 2711. The population was limited to married women because employment data were available only from the mothers' questionnaire. This restriction caused the number of Black mothers eligible for analysis to be so small (n = 399) that they were excluded from the analysis.

Two sets of analyses were conducted to distinguish between the effects of work characteristics on fetal growth and on gestational age, since the two conditions are due to different physiologic processes.[3] For analyses in which term low birthweight was the dependent variable, infants who were clearly preterm (<37 weeks) were removed from the analysis population. Similarly, in analyses of preterm births, infants who were low birthweight (fetal growth retarded) at term (≥37 weeks) were removed. The purpose of this was to exclude infants with identifiable morbidities from the groups to which low birthweight and preterm births were compared. In addition, women who started work after the eighth gestational month were excluded from analyses of preterm births.

Derivation of the analysis samples is show schematically in the Appendix. Each exclusion produced more homogeneous populations with lower risk of adverse pregnancy outcomes. In general, the analysis samples were of lower parity, had more education, received more prenatal care, and gained more weight that the exclusion groups.

Variables

The dependent variables, low birthweight (<2500, ≥2500 g) and preterm delivery (<37, ≥37 weeks), were constructed from the birth certificate source in the NNS. Number of hours worked per week in a company, business or organization was taken from the NNS mothers' questionnaire and categorized as 1 to 20, 21 to 39, and ≥40. Three measures of physical activity were constructed from DOT data. Physical strength was derived from field observations of standing, walking, sitting, lifting, carrying, pushing, and pulling objects; jobs were categorized as sedentary, light, medium, heavy, or very heavy based on these activities.[35] The other physical activities were climbing/balancing and stooping/kneeling/crouching/crawling. A score of 1 for presence or 0 for absence was recorded for each DOT job on these variables.[35]

Six DOT characteristics were used as measures of environmental conditions: (1) work performed outdoors without effective protection from the weather; (2) extreme cold with or without abrupt variations in temperature; (3) extreme heat with or without abrupt variations in temperature; (4) constant or intermittent loud noises; (5) physical hazards (e.g., work on scaffolding, exposure to electrical shock, exposure to toxic chemicals); and (6) elements in the atmosphere (i.e., fumes, odors, dusts, mists, gases, or poor ventilation.) These characteristics were also scored 1 or 0, as above.[35]

DOT job titles do not correspond exactly with the NNS census codes for occupation and industry. To merge the two files, a bridge tape created for this purpose was used. Each DOT value on the bridge tape represented the level of the characteristic for incumbents of a given occupation in the 1971 Current Population Survey. Levels for the physical exertion variable were population means, while values for the remaining DOT characteristics were percentages (of the population in the given occupation with the characteristic present).[36,37]

In this analysis, the scores described above were categorized into low, medium, and high groups, based on distribution in the NNS population. For symmetrical distributions, the lowest and highest deciles were used to designate low and high groups. In cases of asymmetrical distributions with long tails caused by large percentages of jobs in the population that did or did not have the particular DOT characteristic, cut points at the tails were used to designate low or high categories.

Six NNS variables were considered potential confounders.[2] Maternal age, parity, education, and adequacy of prenatal care[38] were categorical variables constructed from birth certificate data. Number of cigarettes smoked per day after confirmation of pregnancy was a continuous variable derived from the mothers' questionnaire. Prepregnant weight adjusted for height was based on data from hospital and mothers' questionnaires. To construct the variable, the National Center for Health Statistics (NCHS) formula, weight/height$^{1.5}$ was applied to the population of all working women.[39] Adjusted weights were categorized as lean (≤14 percentile), normal (15 to 84 percentile), and overweight (≥85 percentile).

Pregnancy complications and weight gain were available in the NNS, but these variables were not controlled in the analysis because effects of work on fetal growth and gestational duration may occur through these conditions. Other potential confounders such as family income, wantedness of pregnancy, and interval since last pregnancy were not used because of missing data. Indicators of previous LBW or preterm birth were not available.

Data Quality

Cases with missing or imputed entries for birthweight, gestational age, and all characteristics of employment were excluded from the analysis. Fewer than 1% of missing data were imputed for the other variables, with one exception, parity at 13.1%. The imputation process and other NNS editing and cleanup processes are described elsewhere.[31,32] Birthweight and gestational age combinations were examined for plausibility according to David's criteria.[40] Forty-five subjects had implausible combinations and were excluded from the analysis. NNS occupation and industry combinations were compared with DOT job characteristics to assess face validity. The investigators concluded that correspondence between the two data sets was acceptable.

Analysis

Analysis was performed by multiple logistic regression using sampling weights. Low-birthweight infants were oversampled in the NNS, and there was differential reporting by age and birth order, resulting in unequal probabilities of selection.[41] Sampling weights were assigned to each birth in each stratum, defined by birthweight, age, and birth order. The analyses reported here involved computing weighted means and proportions and then constructing logistic regression models using the weights. The analysis was conducted using the software PROC RTI LOGIT written for fitting models to complex survey data.[42] This procedure incorporates sampling weights into the estimation of the logistic regression parameters.

Several logistic regression models were constructed with low birthweight as well as preterm delivery as dependent variables. In addition to the work characteristics, the six potential confounders were used as independent variables. Some models included interaction terms for the DOT characteristics by number of hours worked and parity. Generally, a *P* value of .05 was used to designate significance of the F tests of each parameter. Odds ratios and 95% confidence intervals (CI) were also calculated.

Findings

The study population (Table 1) had relatively low percentages of low birthweights, preterm births, and maternal risk characteristics. Each of the analysis populations had similar distributions.

In the population who delivered at term (Table 2), the percent LBW increased directly with number of hours worked, but the only DOT variable distributed in the hypothesized direction was extreme cold. When the effects of confounders were controlled, only number of hours worked was statistically significant. With 1 to 20 hours as the standard, the odds of having a LBW infant were 1.4 (CI = 0.80–2.36) times greater for women who worked 21 to 39 hours, and 1.7 (CI = 1.03–2.68) times greater for women who worked ≥40 hours (Table 3).

Among women who started work at 8 or fewer months of gestation and had infants who were not LBW at term (Table 4), there is no discernible pattern in the distribution of preterm births by number of hours worked or by the DOT characteristics, with one exception: extreme cold. None of the employment characteristics was significant when confounding variables were controlled in logistic regression analysis.

Discussion

The findings suggest that working long hours during pregnancy is associated with low-birthweight deliveries at 37 or more weeks' gestation for married, non-Black women. None of the other characteristics of maternal employment are strongly related to low birthweight at term or to preterm delivery in this population.

The relationship between working long hours and delivery of a full-term, low-birthweight infant is difficult to interpret in light of the other, null, results. The relationship held when each of the other characteristics of work was included in the model, suggesting that long working hours has a strong independent effect on low birthweight. Working 40 or more hours per week may reflect elements of psychological stress or physical fatigue that were not represented in the other variables. Unlike the dramatic findings of Mamelle, et al.[13], analysis of interactions between hours worked and the other work characteristics produced no additional information. However, because interaction analyses were sometimes based on few observations in the combined categories of interest, the possibility cannot be ruled out that working long hours in jobs with identifiable characteristics is the influential factor.

TABLE 1—Distribution of Pregnancy Outcomes and Potential Confounders for 2711 Non-Black Married Women Who Worked during Pregnancy

Characteristic	Percentage of the Population[a]
Birthweight (g)

Some measurement issues also must be considered in interpreting this finding. One is the retrospective nature of the NNS data. In the year following the 1980 birth, respondents probably would have provided accurate information about occupation and industry, but recall of the number of hours worked per week may

have been blurred by time and subsequent events. Also, the number of hours worked per week could have changed during pregnancy, but the NNS questionnaire did not capture this dynamic aspect. Employment data were limited to the mother's chief job. Some women may have worked additional jobs that could have extended the number of hours worked per week. The effects of these deficiencies on the findings would be underestimation of the coefficients of hours worked.

The null findings from analysis of DOT physical and environmental factors should be considered from three perspectives. First, these results are consistent with other studies of American populations,[17–19,22,28] but they contrast sharply with findings from major studies in France[11–13] and Canada.[8,16] Perhaps the working conditions of US women are more favorable for birthweight and length of gestation than those in other industrialized countries, or perhaps the relatively advantaged and homogeneous character of our sample is not comparable to the diverse populations in the French and Canadian studies. Also, the quality of the DOT data (discussed below) may have been inferior to data collected directly, albeit retrospectively, from working women in the French and Canadian studies.

A second possible interpretation is derived from the fact that the low-risk status of the population may have diminished our ability to detect effects of physical and environmental exposures within the sample. Because the study population was sociodemographically advantaged, they may have tolerated physical and environmental stresses of work better than a less advantaged group. Or they may have undertaken jobs with fewer physical demands and more comfortable working environments than less advantaged women. Another analysis of the 1980 NNS data found that advantaged women tended to work in the professional, technical, and managerial sector,[43] where physical and environmental insults are likely to be few. We also found evidence that the study population had some control over work-related exposures. There were considerably higher percentages of women who stopped working in the first 3 months of pregnancy who had jobs categorized as high on each of the DOT factors. This tendency was also found, although not as consistently, for women who worked short (1 to 20) hours.

A third possibility, misclassification bias in DOT data, warrants close attention. The only positive result in this study was based on NNS data, whereas all analyses of DOT variables produced null results. We selected the DOT as our source of employment data because, as an independent source derived primarily from on-site observations, it allowed us to avoid self-report and expert opinion biases in job measurement. The DOT has been used extensively for research[44] and has been shown to correlate reasonably well with another large national employment data base.[45] Linking of macrolevel data bases with individual data is advocated as an informative tool for initial epidemiologic studies. However, an inherent bias toward the null of coefficients derived from multiple regression analysis has been reported.[45] In addition, a number of documentation and procedural problems with data collection and assignment of scores in the DOT have been identified.[34] These problems could have resulted in misclassification of the variables of interest. We attempted to identify misclassification by examining DOT values in each occupation or industry for face validity before any analyses were conducted. Also, after analyses of physical and environmental variables were completed, we created three separate measures of high vs low risk for physical exertion from NNS occupation data only, and repeated the logistic regression analysis with each. Consistent with our DOT findings, none of these measures was associated with either of the outcomes. (The definitions of these variables

and results of the analyses are available from the authors upon request.)

The promise for statistical control of potential confounders in the NNS was substantial, but because of missing data, several critical variables such as income, pregnancy interval, and alcohol consumption were not used. Other key variables (e.g., previous LBW, previous pregnancy complications, psychosocial stress, and physical activity outside of work) were not available. While it is unlikely that control of these factors would have altered the null results, they should be included in future research.

In light of the preceding observations, it is prudent to conclude that non-Black, married American women may face a risk of delivering low-birthweight babies at or near term only if they work 40 or more hours each week. However, the lack of risk associated with other characteristics of work may be a function of measurement error in the DOT data source or of low levels of exposure in this sociodemographically advantaged population. With regard to the potential effects of physical and environmental characteristics in the workplace, this study has taken the logical next step in a progression of epidemiologic investigations that includes retrospective self-reports of job exposures, post hoc assignment of exposures by expert panels, and merging of macrolevel job characteristic files with individual-level data. It is now clear that these less expensive approaches to studying maternal employment and pregnancy outcome are not sufficient. Studies based on high-quality data collected prospectively from the women themselves are imperative. ☐

Acknowledgments

The authors wish to thank Drs. Paul Placek and Ken Keppel of the National Center for Health Statistics for their advice and guidance concerning the 1980 NNS, and Dr. Ken Spenner for consultation on the DOT. Appreciation is also extended to Drs. J. Richard Udry, Karen Gleiter, David Savitz, and Milton Kotelchuck for assistance at several points during the study, to Susan Harris for typing multiple drafts of this paper with characteristic skill and good humor, and to John Feaganes for programming assistance. This research was supported by Grant No. R01-HD-22150 from the National Center for Child Health and Human Development.

The manuscript is based in part on a paper presented at the 116th Annual Meeting of the American Public Health Association, November 1988, Boston, Mass.

Source of Bias in Prenatal Care Utilization Indices: Implications for Evaluating the Medicaid Expansion

Greg R. Alexander, MPH, ScD, Mark E. Tompkins, PhD, Donna J. Petersen, MHS, ScD, and Judith Weiss

ABSTRACT

Background: Recent expansions in eligibility for coverage of prenatal care services by the Medicaid program reflect national initiatives to improve pregnancy outcomes. This study investigates the potential impact that completeness of reporting of prenatal care and gestational age variables and strategies to impute missing data may have on evaluations of the Medicaid expansion.

Methods: This study, examining 15 years of vital record data from a single state and comparing 1 year of data from four mid-Atlantic states, selected single live births to resident mothers for analyses. The "day 15" and the "preceding case" methods were used to impute missing gestational age data.

Results: Considerable temporal and geographic variation was detected in completeness of reporting of variables used to construct prenatal care indices. After imputing values for cases with missing data, the proportion of cases for which adequacy of prenatal care utilization could not be determined ranged from 3% to 24% among the states investigated. For those cases where gestational age data could be imputed, the distribution of prenatal care utilization was not markedly disparate from those cases with complete reporting of gestational age.

Conclusions: The results indicate that variations in reporting, decisions regarding the treatment of missing data, and the choice of the denominator can alter prenatal care utilization percentages and have implications for evaluations of the impact of the recent Medicaid expansion on prenatal care utilization. (*Am J Public Health.* 1991;81:1013–1016)

Introduction

Recent expansions in eligibility for coverage of prenatal care services by the Medicaid program reflect policy initiatives to meet Year 2000 national health objectives related to low birthweight and infant mortality.[1] Increased utilization of prenatal care has been associated with improved pregnancy outcomes.[2–7] In an effort to reduce financial barriers to prenatal care, Medicaid eligibility criteria were raised in 1990 to 133% of the federal poverty level, with state options to extend coverage to 185% of poverty. One focus for evaluation of this policy is the extent to which changes in eligibility for state Medicaid coverage will increase utilization of prenatal care and ultimately decrease low birthweight percentages and infant mortality rates.[8]

Prenatal care utilization is commonly measured by composite indices, the most notable being the Kessner Index of Adequacy of Prenatal Care.[2] This index considers the month prenatal care began, the number of prenatal care visits received, and the gestational age at delivery to categorize prenatal care utilization as adequate, intermediate, or inadequate. The adequate category includes cases with a first trimester initiation of care and prenatal care visits that are more than or equal to a recommended number for a pregnancy of a given duration. More visits are required as gestation increases. Initiation of care in the second trimester or an earlier initiation with less than the number of visits recommended to achieve the adequate category is termed intermediate care. Cases with no prenatal care, initiation of care in the third trimester, or an earlier initiation of care with less than the number of visits stipulated to achieve the intermediate category are labeled inadequate care. Modifications and alternatives to this index have been proposed[3,9–11] and used to investigate the relationship of prenatal care to a variety of pregnancy outcome measures.[2–6,9] Unfortunately, descriptions of these indices have often failed to specify how missing or implausible data should be handled.

The treatment of missing data in the construction of these indices is an important issue. In the Kessner index, cases with missing prenatal care data are classified as having inadequate prenatal care utilization.[2] Further, while various methodologies have been suggested to impute missing gestational age data,[12–15] a convention for the use of imputed gestational age data in the calculation of prenatal care utilization indices has not been established. The date of last menstrual period (LMP), needed to calculate the gestational age interval, has been estimated to be incomplete on approximately 20% of the nation's birth certificates.[12]

State-specific analyses of trends in prenatal care utilization before and after adoption of Medicaid options and comparisons of prenatal care among states with varying eligibility levels may be sub-

TABLE 1—Percentage of Missing Components of Prenatal Care Utilization Index by 5-Year Groups: 1974–1988 South Carolina Resident Single Live Births

Missing Component	1974–1978	1979–1983	1984–1988
		Percent	
Trimester that prenatal care began[a]	5.99	0.74	1.10
No. of prenatal care visits[b]	1.09	0.62	1.04
Gestational age interval[c]			
No imputation	16.33	5.31	6.91
Day 15	2.09	1.97	2.21
Preceding case	2.04	1.92	2.15
Total missing[d]			
No imputation	19.05	5.37	7.03
Day 15	7.50	2.21	2.63
Preceding case	7.47	2.18	2.58

[a] Includes cases with a not-stated month prenatal care began or with a stated but nonspecific response, e.g., an actual month (January through December).

[b] Includes cases with a not-stated number of visits or with stated visits of 50 or more.

[c] Includes cases with an incomplete date of last menstrual period or a missing gestational age interval value after imputation, where indicated. Gestational age intervals <20 or >50 weeks are treated as missing.

[d] Includes cases with a missing value for any of the prenatal care utilization index component variables, i.e., trimester prenatal care began, number of prenatal care visits, and gestational age interval from last menstrual period.

TABLE 2—Prenatal Care Utilization Percentages by Gestational Age Imputation Method and 5-Year Groups: 1974–1988 South Carolina Resident Single Live Births

Prenatal Care Groups	1974–1978 (N = 237 347)	1979–1983 (N = 251 247)	1984–1988 (N = 256 175)
No imputation			
Adequate	48.36	55.81	53.61
Intermediate	24.43	29.23	28.45
Inadequate/missing	27.21	14.97	17.94
Missing[a]	19.05	5.37	7.03
Inadequate	8.17	9.59	10.91
Day 15			
Adequate	54.27	57.42	55.88

Inadequate/missing	17.27	12.23	14.16
Missing[a]	7.50	2.21	2.63
Inadequate	9.77	10.02	11.53
Preceding case			
Adequate	54.27	57.43	55.89
Intermediate	28.48	30.36	29.98
Inadequate/missing	17.25	12.21	14.13
Missing[a]	7.47	2.18	2.58
Inadequate	−9.78	−10.03	−11.55

[a] Includes cases with a missing value for any of the prenatal care utilization index component variables, i.e., trimester prenatal care began, number of prenatal care visits, and gestational age (after imputation where indicated).

Note: Because of rounding, columns may not total 100%.

ject to bias due to changes in the completeness of reporting of the variables used to construct these indices and in methodologies employed to impute missing data. This study investigates the potential impact that completeness of reporting of prenatal care and gestational age variables and strategies to impute missing data may have on evaluations of the Medicaid expansion. Two study designs have been employed: (1) examining 15 years of data from a single state, and (2) comparing 1 year of data from four eastern states.

Data and Methods

Computerized South Carolina live birth files for the years 1974 to 1988 were used for the first component of this investigation. For the second component, additional data from three mid-Atlantic states with varying levels of completeness of reporting of gestational age were drawn from the Department of Health and Human Services (DHHS) Region III Perinatal Information Consortium's 1987 Live Birth File.[16] Single births to resident mothers were selected for both analyses.

Gestational age was calculated as the interval from the date of last normal menses to the date of birth and was truncated into completed weeks.[17] Two strategies were employed for imputing missing gestational age data.[15] The "day 15" method imputes a value of 15 for the day of last normal menses for those births for which this single piece of information prevents the calculation of the gestational age interval. The "preceding case" method imputes gestational age by inserting the calculated gestational age interval value of a preceding birth with a corresponding month of LMP, 500-g birthweight interval, and race of mother.

Results

Table 1 displays the proportion of South Carolina cases with missing prenatal care and gestational age information for three 5-year periods. Nearly 6% of the cases in the 1974 to 1978 period exhibited missing or nonspecific data on month or trimester of pregnancy that prenatal care began. Missing gestational age data were found for more than 16% of the cases in the 1974 to 1978 period, but dropped markedly in later periods. After imputation methods were employed to recapture cases with incomplete dates of LMP, gestational age was still missing for approximately 2% of the cases in each period.

Table 2 presents percentages of prenatal care utilization employing three different treatments of missing gestational age data (no imputation, day 15, and preceding case). Based on no imputation, adequate prenatal care utilization was lowest in the 1974 to 1978 period (48.36%). When cases with missing data were combined with the inadequate category, the percentages based on no imputation varied across the three periods from 27.21% to 14.97% to 17.94%. The separate inadequate category increased from 8.17% in the 1974 to 1978 period to 10.91% for 1984 to 1988. There is little appreciable difference in the prenatal care distribution percentages produced by the two alternative methods for imputing missing gestational age values.

The next phase of the analysis utilized 1987 data from four states. The preceding case method was selected to impute missing gestational age values. Table 3 depicts by state the percentages of cases with missing gestational age data, before and after imputation, and missing prenatal care initiation and visit data. States B and C revealed a relatively higher proportion of missing gestational age data, 20.10% and 17.58%, respectively. While imputation markedly reduced this proportion in state C (5.73%), it had little impact in state B, where most cases with missing gestational age data were missing the entire date of LMP, not just the day value.

Prenatal care utilization percentages by state and gestational age imputation group are displayed in Table 4. These percentages are calculated in two different ways. In part A, percentages are based on a denominator of all live births with a separate category for cases with missing prenatal care or gestational age values after the application of the indicated gestational age imputation method. In part B, after imputation where indicated, cases with missing prenatal care and gestational age data are excluded, and percentages are based on a denominator of cases with the prerequisite in-range data elements needed to compute the index.

For states A and B, the imputation of gestational age had little appreciable effect on prenatal care percentages based on all cases (Table 4, part A). However, the proportion of total missing cases was noticeably reduced by imputing gestational age in the other two states. When calculations only included cases with in-range or imputed data values (Table 4, part B), the use of the gestational age imputation method had little appreciable impact on the prenatal care utilization percentages. This result suggests that the prenatal care utilization distribution for those cases for which a missing gestational age value could be imputed was only slightly less adequate than that of cases with complete gestational age data. For example, in state C, where gestational age was imputed for more than 10% of the cases, the adequate percentage was 71.55% before imputation and 71.06% afterward.

TABLE 3—Percentage of Missing Components of Prenatal Care Utilization Index by State: 1987 Resident Single Live Births

Missing Component	State A	State B	State C	SC[a]
Trimester that prenatal care began[b]	4.96	4.73	2.84	0.88
No. of prenatal care visits[c]	2.12	6.68	2.94	1.17
Gestational age interval[d]				
No imputation	5.10	20.10	17.58	7.26
Preceding case	4.69	20.01	5.73	2.16

[a]SC = South Carolina

[b]Missing trimester in pregnancy prenatal care began category includes cases with a not-stated month prenatal care began.

[c]Missing number of prenatal care visits category includes cases with a not-stated number of visits or with stated visits of 50 or greater.

[d]Missing gestational age category includes cases with an incomplete date of last menstrual period or a missing gestational age interval value after imputation, where indicated. Gestational age intervals of <20 or >50 weeks are treated as missing.

TABLE 4—Prenatal Care Utilization Percentages by Imputation Method and State: 1987 Resident Single Live Births

[b]Includes cases with a missing value for trimester prenatal care began, number of prenatal care visits, or gestational age (after imputation where indicated).

Note: Because of rounding, columns may not total 100%.

Discussion

These data indicate that variations in reporting, decisions regarding the treatment of missing data, and choice of denominator can alter prenatal care utilization percentages. The true potential impact of the Medicaid expansion on prenatal care utilization may be obscured due to these factors. Therefore, evaluations of the Medicaid expansion should include a thorough examination of reporting completeness, a disclosure of strategies employed for imputing missing data, and a description of the methods used to calculate prenatal care percentages.

These data further suggest that it is unwise to categorize cases with missing prenatal care or gestational age data in the inadequate care group. The distribution of prenatal care utilization was not markedly disparate for those cases with imputed gestational age data and those cases with complete reporting of gestational age. This result argues both for employing gestational age imputation strategies and not assuming that cases with missing data had inadequate prenatal care utilization. While the prenatal care utilization of those cases with missing data remains unknown, estimates of inadequate prenatal care usage that include cases with missing data may be inflated.

Whether prenatal care percentages should be calculated from all cases or only those for which the index can be generated is illustrated by data from state B. Based on all cases, 57% of women delivering in that state were placed in the adequate category. Excluding cases with missing data from the calculation resulted in a placement of 75% of women into the adequate category. The ease with which prenatal care percentages can be manipulated into adequate and other than adequate categories should not be ignored, given the political context of an impending evaluation of a major public policy initiative. If we assume that cases for which the index can be calculated are roughly similar or only marginally better in their prenatal care utilization patterns than those without the prerequisite data, the 75% figure may be a better estimate of the proportion of all births in the state with adequate prenatal care utilization. To alternatively assume that most cases with missing data have less than adequate utilization of prenatal care is unrealistic in areas with large proportions of missing data. While cases with missing gestational age data have been shown to display higher risks of poor pregnancy outcomes,[15] all cases with missing data will not necessarily exhibit adverse outcomes or less than adequate prenatal care utilization. Care should be taken in the analysis and reporting of these percentages to ensure that large missing group percentages are not used to represent individuals with less than adequate prenatal care utilization.

The choice between the day 15 or the preceding case method to impute missing gestational age data appears to have little impact on prenatal care utilization distributions. While the day 15 method has been noted to inflate preterm percentages in comparison with the preceding case method,[12,15] the amount of bias introduced by this approach appears insufficient to produce a prenatal care utilization distribution markedly different from that obtained by the preceding case method.

Prenatal care utilization indices are a useful but crude surveillance tool for assessing needs and evaluating programs and policy. Evaluation of the Medicaid expansion by these indices is a heuristic attempt to provide accountability for a major policy initiative that may enhance maternal and infant health in ways not easily appraised by available health measurement tools. Because the components of these indices are subject to reporting bias, and because important characteristics of prenatal care (e.g., quality, comprehensiveness, and continuity) are not considered, it is imperative that these indices be prudently employed in evaluation efforts and be continually scrutinized for bias.

Credible data for programmatic efforts and policy discourse require both accurate and complete reporting and logical and systematic analysis. The three component variables of prenatal care utilization indices contain potentially large measurement error. Vagaries in analytical methods used to compute these indices can further add to the uncertainty regarding the proposed relation between prenatal care utilization and pregnancy outcome and the possible impact of policy initiatives. These methodological concerns require ongoing attention, but they should not be used to divert attention from critically needed efforts to ensure that all women have access to and are encouraged to use prenatal care. □

Uncompensated Hospital Care for Pregnancy and Childbirth Cases

Terrell W. Zollinger, DrPH, Robert M. Saywell, Jr, PhD, MPH, and David K. W. Chu, PhD

ABSTRACT

Background: The large number of medically indigent patients in the United States is a major concern to policymakers and may be due to recent increases in the number of uninsured people. The purpose of this study was to identify the factors that affect the amount of unpaid hospital charges for services provided to pregnant women.

Methods: Individual and hospital data were collected on a representative set of 235 pregnancy and childbirth patients with unpaid hospital charges from 28 hospitals in the state of Indiana.

Results: Most of these patients did not have insurance coverage (63.8%), yet the majority were employed in the public or private sector (72.3%). Over half (55.5%) of the total uncompensated care amount for this group was from the $1000 to 2499 debt category. The median charge for these patients was $1468, of which the typical hospital was able to collect only 25.5%.

Conclusions: The findings support the belief that any national effort to expand the availability of health insurance coverage to women through increased employment will not totally eliminate the uncompensated care problem. The findings also indicate that rural hospitals face the uncompensated care problem mainly because a significant portion of rural patients are without adequate health insurance coverage. (*Am J Public Health.* 1991;81:1017–1022)

Introduction

The large number of medically indigent patients in the United States, a major concern to policymakers, can be attributed to increases in the number of uninsured and underinsured people. This increase in indigent patients, especially pregnant women, has created additional financial burdens for hospitals. In our earlier studies examining uncompensated care patients in hospitals,[1,2] we found that pregnancy and childbirth accounted for the largest proportion of uncompensated care cases (19.1%) and the largest percentage of uncompensated dollar amounts (17.4%). Researchers have found that a lack of adequate prenatal care leads to low birthweight in infants, which in turn contributes to a higher incidence of infant mortality.[3–7] Other research indicates that younger women who have lower incomes and less education, reside in rural areas, or are Medicaid recipients tend to have less access to prenatal care.[3,6,8–11] Until recently, the eligibility requirements for Medicaid had been increasing, and as a result, relatively fewer women and children were being covered by Medicaid.[3,12–15] Denied access to prenatal care increases the hospital cost because of higher frequency of subsequent complications in delivery and perinatal care, which leads to even higher amounts of unpaid hospital bills.[4,7]

In this study, patients belonging to the pregnancy and childbirth subset of the original sample of uncompensated care inpatients[1] were examined to identify the factors that affect the amount of unpaid hospital charges for services provided to pregnant women. The identification of these factors could lead to the development of policies designed to remove existing patient, provider, and system barriers to prenatal care[3,4–6,16–18] and facilitate medical care access for pregnant women.

Methods

Uncompensated care normally consists of bad debt, charity care, contractual allowances, and courtesy discounts. The uncompensated hospital care costs considered in this study were only those originating from the bad debt and charity care categories. Medicare and Medicaid patients were also excluded because bad debts arising from their failure to pay deductibles are reimbursed by the Medicare and Medicaid programs. Bad debts are amounts due from patients who are expected to pay, but for some reason do not. Charity care is care that is provided to patients who, prior to admission, are generally identified as unable to pay and who are not expected to pay. The hospitals in this study did not consistently classify patients as "bad debt" or "charity care" cases.

The sampling scheme used in this study selected a representative set of Indiana hospitals as well as a representative set of patients from those hospitals with unpaid hospital charges. First, a stratified

random sample based on urban/rural classification of 27 of the 115 acute care general hospitals in Indiana was drawn. Additionally, a tertiary teaching hospital was purposely included in the study to represent that class of hospital. Of the 28 hospitals, 14 (50%) were classified as urban, 16 (57.1%) as small (fewer than 150 beds), 5 (17.9%) as medium (150 to 399 beds), and 7 (25%) as large. All large hospitals were located in urban areas. Second, once the sample of hospitals was identified, a systematic random sample of those patients who did not pay all of their hospital bill during the 1986 calendar year was selected by using a 1/20 sampling fraction. This sampling scheme identified 235 (13.9%) patients hospitalized with the primary diagnosis of pregnancy and childbirth who received uncompensated care. Total revenue for the study hospitals was compiled from the *1986 Indiana State Board of Health Financial Disclosure Report.*[19]

The pregnancy and childbirth cases receiving uncompensated hospital care in our sample were classified by urban/rural hospital location on the basis of whether the hospital was located within a Standard Metropolitan Statistical Area and by amount of the unpaid hospital bill of the patient.

The data were analyzed with the Student's *t* test and analysis of variance to test for significant differences in means; tests for independence were assessed with the chi-square test. The criterion for statistical significance was $P < .05$.

A multiple regression model was constructed by using the percentage of the charges left unpaid as the dependent variable. Potential explanatory variables were included in a stepwise-forward procedure (using $P < 0.10$ for inclusion) to determine which variables had a significant impact on the dependent variable, controlling for the other variables. Since the interval-ratio scale variables used in the model were skewed, log transformed versions of these variables were used in the model to improve their normality.

The results of this study should be interpreted cautiously because of the inherent limitations of the study data. This study was partly based on secondary patient data reported to the hospital by individual patients upon hospital admission. Also, the employment data did not distinguish between part-time and full-time employment, they merely indicated whether a person was reported as being employed or not.

Results

As shown in Table 1, 61.9% of the 235 cases had unpaid hospital charges of $1000 or more. Fewer than one fourth of the cases (22.6%) left unpaid charges under $500. Nearly two thirds (63.8%) were treated in urban hospitals with 41.7% treated in large hospitals, another 41.7% in small hospitals, and only 16.6% treated in medium-sized facilities. On average, 79.1% of the pregnancy and childbirth patients with unpaid bills originated from the county in which the hospital was located. There were no statistically signincant relationships between the distribution of the unpaid amount and the location of the hospital, the size of the hospital, and the number of uncompensated care patients originating from the same county as the hospital.

The study group received a total of $311 382 in uncompensated care (Table 2). Individual uncompensated care amounts ranged from $4 to $7975. Less than 5% of the total uncompensated care amount was from debts smaller than $499; over half (55.5%) of the total uncompensated care amount was from the $1000 to 2499 debt category. Patients in this study with unpaid hospital charges of $5000 or more were responsible for only 6.4% of the uncompensated care.

The total hospital charges for these patients was $469 999, of which study hospitals were only able to collect an average 25.5%. The median total hospital charges for these cases was $1468 with a median uncollected amount of $1226 (83.5%). Patient characteristics, as summarized in Table 3, reveal that the typical pregnancy and childbirth patient with unpaid hospital charges was 23.3 years old, was married (61.8%), spent 3.2 days in the hospital, and was discharged to self/home care (84.7%). The age and marital status of the patients showed no significant relationships with the amount of the hospital bill left unpaid. As the length of stay increased, so did the amount of the hospital bill left unpaid. In addition, a larger proportion of the patients with greater amounts of unpaid hospital bills were discharged to long-term health care facilities. Those with insurance coverage tended to have fewer unpaid hospital charges, and those without insurance tended to leave larger amounts unpaid.

The majority (77.6%) of the study patients reported to be employed in either the public or private sector or self-employed, yet only 36.2% had some form of health insurance coverage. The unemployed group left significantly higher amounts of their hospital bill unpaid than the patients who were employed.

A second analysis evaluated patient and hospital variables by dollar amount of uncompensated care as shown in Table 4. Nearly two thirds (63.2%) of the uncompensated amount was reported by urban hospitals. However, the mean uncompensated care dollar amounts per case did not

differ significantly for the rural and urban hospitals. Large hospitals incurred 40.8% of the uncompensated care dollars; medium-sized hospitals, 16.1%; and small hospitals, 43.1%. There was no significant difference in the mean uncollected amounts between the three classes of hospital size.

Self-pay patients accounted for 71.0% of the dollar amount of unpaid hospital bills, compared with 16.4% for commercial and Blue Cross patients. Self-pay patients also accounted for significantly larger mean uncollected amount (along with the "other insurance" category). Of the total uncompensated amount, only 26.5% was generated by those who were unemployed while over two thirds (68.7%) was generated by people employed in the private or public sector. However, there was not a significant difference between the employment groups in the mean amounts of uncompensated care. Married patients accounted for 61.3% of the uncompensated dollar amount, but the mean uncompensated amounts did not differ significantly between the marital status groups.

Table 5 presents uncompensated care information by hospital location. Of the cases treated in urban hospitals, most (65.3%) were in large facilities. Slightly more urban than rural hospital patients resided in the county the hospital was located in, but the differences were not statistically significant.

The study subjects from the urban and rural hospitals did not differ significantly with respect to age, marital status, average length of stay, or employment status. However, cases with unpaid hospital charges reported from rural hospitals were more likely to be self-insured (74.1% vs 58.1%) and more likely to be discharged to self/home care (95.3% vs 78.7%). The median charge for pregnancy and childbirth care for the group who did not pay all of their hospital charges was somewhat higher for those treated in urban hospitals. However, the mean uncollected amount did not differ between the urban and rural hospitals because of the higher collection rates of the urban hospitals.

The multiple regression procedure indicated that two insurance categories: "Commercial and Blue Cross" and "Other" (i.e., HMO, PPO) contributed the

greatest amount to the model. The amount of the total charge to the patient was also significant at the $P < .10$ level. These three variables accounted for nearly 40% of the variation in the percentage of the hospital charges left unpaid. For all three variables, the partial regression coefficients were negative; this indicated that if the patient had some form of insurance, the percentage of the bill left unpaid was lower, and if the total charge was higher, the percentage left unpaid was also lower. Demographic characteristics of the patients (age, marital status, employment) were not found to be important factors in the model. Neither were the discharge status and the length of stay. The two hospital characteristics, urban/rural status and total revenue, were also not important factors in the model.

Discussion

The study of pregnancy and childbirth patients who do not pay all of their hospital bill resulted in three findings that suggest a need to further examine existing public policy as it affects these women: (1) the majority (63.8%) of the pregnancy and childbirth patients who left part or all of their hospital bill unpaid did not have insurance; (2) pregnancy and childbirth patients tended to have overall larger dollar amounts of bad debts relative to other uncompensated care patients; and (3) the collection experience was lower for pregnancy and childbirth patients than for patients from all diagnosis groups as previously reported.[1,2]

The data indicate that the patient's insurance coverage was the major factor in a facility's ability to recover its total charges. Only a third of the patients in this study had any insurance coverage. It is remarkable that 63.8% of the pregnancy and childbirth patients with unpaid hospital charges had no insurance coverage as compared with 44.6% who had no insurance in the sample of patients from all diagnosis groups found in our earlier studies.[1,2] This is a high proportion of uninsured patients in light of the fact that over three fourths of the pregnancy and childbirth patients were reportedly employed. There are three possible explanations: (1) some of the employers do not offer health insurance benefits to their employees, (2) the individual cannot afford or for other reasons chooses not to purchase the insurance, (3) or the insurance policies do not cover pregnancy and childbirth-related hospital services (there may be a waiting period for maternal benefits to take effect). Some of the insurance plans may have high coinsurance or deductibles for pregnancy-related health care, and those patients with insurance coverage may be unable or unwilling to pay their portion of the hospital bill.

These findings, although based solely on the findings of one state, may support the belief that any national effort to expand the availability of health insurance coverage to women through employers will not totally eliminate the uncompensated care problem for maternal and child health patients and the hospitals providing the care. The fact that the majority of the women in this group were employed (77.6%) points to a different set of problems. A policy expanding availability should be considered a step in the right direction to reduce the amount of uncompensated care provided by hospitals. Yet the greater problem may be that employed women in this group cannot afford the insurance premiums and thus remain uninsured or underinsured. On the other hand, if high coinsurance amounts and large deductibles are problems for those with insurance (36.2%), changes in the shared portion would also be required to reduce the amount of the hospital charges determined to be the responsibility of the patients themselves (i.e., lower copayment or deductible amounts).

A second major contrast between the results found in this study of pregnancy and childbirth patients and our previous study of all patients was that pregnancy and childbirth patients tended to have larger total uncompensated dollar amounts. Fewer than 5% of the pregnancy and childbirth cases had uncompensated care amounts of less than $500 compared with 39.2% in the sample of patients from all diagnosis groups. Over one half of the pregnancy and childbirth cases had uncompensated care amounts between $1000 and $2499, compared with only 29.2% in the overall study. This clearly indicates that pregnancy and childbirth patients represent a serious financial problem to the hospital.

The third finding shows that of the total charges to pregnancy and childbirth patients, only a small portion was eventually collected (25.2% compared with 38.8% overall). This points to an apparent inability and/or unwillingness of the facility to seek recovery of these outstanding balances. Hospital administrators may perceive that aggressively pursuing these unpaid bills may be futile and/or not cost-effective on an individual basis, even though collectively such cases represent a large proportion of the hospital's total uncompensated care. The indirect cost of collecting these debts, in the form of poor publicity generated in the community, may be seen as somewhat counterproductive to the mission of the facility.

Although the median dollar amount charged by rural facilities was lower than that charged by urban facilities, the collection rate was also lower, thus the median uncollected amount was approximately the same. These findings indicate that rural hospitals face the uncompensated care problem mainly because a significant portion of rural patients are without adequate health insurance coverage. If this is the case, there is a need to expand insurance coverage to the rural population to ensure that this population has access to comprehensive health care.

The patterns seen with uncompensated hospital care may be related to the overall problem of inadequate prenatal care. Some of the patients who leave hospital bills unpaid may also have failed to obtain adequate prenatal care. The major factor thought common to both problems involves financial barriers to care. Thus hospital administrators are faced with the difficult question of how aggressively they should seek payment for services rendered. Aggressive collection efforts may discourage the medically indigent, higher risk women from seeking prenatal care. However, if adequate prenatal care is not provided by the hospital (even at a loss), high-risk women are more likely to have medical complications. Thus, when these women are finally admitted into the facility, the result could be an even greater amount of uncompensated care than if they had received adequate prenatal care initially. Evidence shows that better prenatal care would be obtained if the financial barriers for patients were removed.[3,6,8–11]

Increasing health insurance coverage for the patients, and not just increasing the availability of health insurance for both those employed and unemployed, is a possible solution. However, an increase in insurance coverage entails more costly public policy interventions. One public policy option could include requiring mandatory insurance coverage to be provided (not merely made available) by employers. However, this option may result in higher cost of goods and services, making American businesses even less competitive in the international arena than they already are. A second option would be to increase Medicaid coverage and eligibility. This option would result in higher taxes and/or the shifting of resources from other public programs into health care programs. These possible consequences must be considered before any policy is enacted. However, we need to recognize that presently a large part of the burden of providing prenatal and hospital care to the indigent population falls on hospitals and only more indirectly on business or the taxpayer. If inroads are to be made into solving the infant mortality problems, policies regarding equitable compensation to hospitals must also be addressed. Further research is needed to examine the demographics and collection experiences of all hospital patients so that the characteristics of the paying and the nonpaying patients can be distinguished. ☐

Report Cites Vaccine Shortage in Health Centers Serving Poor Children

In 1990, the year that there were to be no more than 500 cases of measles nationally under goals set in 1979 by the Surgeon General, more than 25 000 cases of measles were reported. As community health centers grappled with shortages of government-supplied vaccines, according to a new Children's Defense Fund report, *Vaccine Supply and Low Income Children: Barriers Faced by Community and Migrant Health Center Patients*, more children died from measles in 1990 than in any year since 1971.

"Measles is a particularly sensitive and early indicator of the nation's eroding childhood immunization system because the disease is so contagious," said Sara Rosenbaum, director of CDF's health division. "Other diseases such as mumps and pertussis are showing similar surges. The current epidemic of utterly preventable childhood illness and death must be halted. We have only our lack of collective national will to blame for this crisis."

Yet in the midst of the worst measles outbreak in more than 20 years, the CDF report finds that federally funded community health centers that provide primary health care to nearly 3 million poor children have been experiencing shortages of government-supplied vaccines critical to immunizing poor children against childhood diseases. As a result, the youngest health center patients, all of which live in medically underserved urban and rural communities, run a high risk of inadequate vaccination.

Rosenbaum recommended a number of steps to alleviate the crisis in vaccine shortages and immunization delivery. One step is the immediate expansion of the Centers for Disease Control's (CDC) vaccine contract purchasing program by $80 million.

Rosenbaum said: "Currently CDC simply does not have enough publicly purchased vaccines to meet the needs of both state and local health agencies and health centers. All of these clinics must be assured an adequate supply of vaccines at the lowest available price. The CDC purchase and distribution contract system must be expanded at least to meet the needs of all publicly funded health care providers rather than forcing those providers to stop vaccinations or to purchase on the private market at four times the cost."

Moreover, according to the report, numerous health centers reported that state Medicaid agencies were not reimbursing them for the cost of vaccines administered to Medicaid-enrolled children which they were forced to purchase privately when their health department supplies were exhausted. Others reported that some states refused to cover certain vaccines at all despite federal mandates.

Rosenbaum pointed out that the National Vaccine Advisory Committee in January concluded that low vaccination rates and disease outbreaks are chiefly the result of systemic breakdowns, not parents' willful or negligent failure to seek vaccinations.

The CDF report reviews a number of systemic problems that have led to the growing vaccine crisis, including soaring vaccine costs over the past decade, the increasing number of private physicians who no longer vaccinate children in their offices, increased childhood poverty, and growth in the number of children with no health insurance.

"The childhood immunization crisis is a stark reminder of the severe shortage of basic health services that persist in countless medically underserved urban and rural communities," Rosenbaum said.

If recent trends continue, by the end of the century US immunization rates for infants and toddlers will lag behind those of dozens of Third World countries. Among the 16 countries with higher immunization rates than ours in 1988 to 1989 (as measured by 1-year-olds fully immunized against polio) were Bulgaria, Hungary, Greece, Brazil, China, Mexico, North Korea, Chile, and Rumania. Among the 55 countries with infant polio immunization rates higher than the United States non-White rate were Albania, Cuba, Jordan, Tunisia, Colombia, Iran, Malawi, Botswana, Maritius, Sri Lanka, Mongolia, Jamaica, and Rwanda.

Sociodemographic Factors and the Quality of Prenatal Care

Mary Jo Hansell, BSN, DrPH

ABSTRACT

Background: In this study, maternal sociodemographic factors are examined in relationship to the quality of prenatal health services US women receive.

Methods: Data from the 1980 National Natality Survey and 1980 Fetal Mortality Survey were used for the analysis. Indicator variables for prenatal care quality are the percentages of prenatal visits at which blood pressure and urine were tested, the performance of hemoglobin or hematocrit tests, and the presence or absence of advice regarding salt restriction and diuretics usage during pregnancy.

Results: Distribution of the basic examinations in prenatal care vary according to marital status, parity, education, and residence in a metropolitan or nonmetropolitan county. The advice received concerning salt and diuretics usage was also influenced by sociodemographic variables.

Conclusions: The analyses reveal that prenatal care is not of even minimally acceptable quality for many women. (*Am J Public Health.* 1991;81:1023–1028)

Introduction

Numerous efforts have been made to assess the adequacy of prenatal care obtained by pregnant women in the United States. The adequacy of prenatal care can be measured by examining two components: (1) the timing and quantity of visits and (2) the quality of health services. With little exception to date,[1] studies of the adequacy of prenatal care have concentrated on the first component. Researchers have found that about one third of pregnant women obtain too few prenatal visits or start prenatal care too late. The groups getting the most inadequate care are teenagers, minorities, the least educated, the unmarried, and the poor[2–5] (P. J. Placek, unpublished manuscript, May 15, 1987; a more extensive report on this topic was prepared for the Institute of Medicine by Paul Placek, PhD in his private capacity, with appropriate clearances, and no official support or endorsement by his employer is intended or inferred.) Based upon data from the 1980 National Natality Survey (NNS) and the 1980 National Fetal Mortality Survey (NFMS), this research adds measures of quality to the study of the adequacy of prenatal care in the United States.

Women have varying degrees of control over the timing and quantity of prenatal health services they obtain, because sociodemographic attributes and health beliefs affect their utilization patterns. (When asked about barriers to obtaining adequate prenatal care, 39% of the Medicaid recipients and uninsured women interviewed by the US General Accounting Office cited attitudinal barriers, e.g., not wanting to tell others, being afraid of the pregnancy, and being afraid of the medical tests.)[6] Once a woman has chosen her physician, control over the quality of her health care shifts almost completely to the provider. Theoretically, the woman's sociodemographic attributes should not affect the quality of the services received.

The specific research questions to be answered are whether prenatal care recipients obtain basic examinations recommended by the American College of Obstetrics and Gynecology (ACOG), whether women receive appropriate medical advice concerning the use of salt and diuretics during pregnancy, and whether variability in the quality measures (surveillance and advice) corresponds to maternal sociodemographic characteristics.

ACOG recommends that all pregnant women receive both blood pressure examinations and urine tests, for protein and sugar, at every visit and that hematocrit and hemoglobin levels be assessed at least once during prenatal care.[7] Actual practices are compared to these standards of care.

Although attitudes about salt use in pregnancy had changed over time, by 1977 the ACOG had set the standard that normal women should use salt at the level preferred.[7,8] In other words, physicians should not normally advise salt restriction. Administration of diuretics during pregnancy may be acceptable treatment of underlying hypertensive disease but is not approved for normal pregnancy or for preeclampsia.[9,10] The kinds of advice

TABLE 1—Explanatory Variables Included in the Regression Models[a]

Variables	Explanation
Maternal sociodemographic factors	
Age	Number of years of age at delivery
Non-Hispanic White[b]	Non-Hispanic White racial-ethnic group
Black[b]	Black racial group
Native American[b]	Native American Indian racial-ethnic group
Asian/Pacific Islander[b]	Asian or Pacific Islander racial-ethnic group
Education	Number of years of education with final value of 17 or more years[c]
Graduate	17 or more years of education
Married	Married at delivery
Parity	Number parity at start of current pregnancy
Metropolitan	Lived in metropolitan county at time of delivery
Prenatal care (PC) quantity and timing measures[d]	
Month PC begun	Month of pregnancy that first prenatal visit made
Number visits	Number of prenatal visits with final value of 30 or more visits[e]
Top visits	30 or more visits made
Maternal health status factors[f]	
High BPs %	Percent of prenatal visits at which blood pressures were above 140/90
Any complications	One or more of a list of complications were noted by the physician
Hypertension	Physician-identified hypertension
Preeclampsia	Physician-identified preeclampsia
CV–renal disease	Physician-identified cardiovascular–renal disease
Prepregnancy weight	Physician-reported maternal weight before pregnancy

[a] Variables are dichotomous (0 = no; 1 = yes), except as indicated.
[b] Compared with Hispanic White (the omitted category).
[c] The NNS and NFMS collapsed the top values to 17 or more years.
[d] Included as controls in the regressions of blood testing, advice about salt restriction, and advice about diuretics usage.
[e] The NNS and NFMS collapsed the top values to 30 or more visits.
[f] Included as controls in the regressions of advice about salt restriction and diuretics usage.

given by physicians regarding salt restriction and diuretics usage are compared with these expert recommendations.

Taffel and Keppel,[11] using the 1980 NNS, examined advice given by physicians about weight gain. They found that the majority of married mothers were given no weight gain limit or were advised to gain less than the amount currently recommended by nutritional experts. The advice varied according to race, educational background, parity, and prepregnancy weight.

Methods

Data

The National Center for Health Statistics based the NNS and NFMS on a complex random sample of 9941 live births and 6386 late fetal deaths that occurred in the United States during 1980.[12] Late fetal deaths are defined as fetal deaths with gestations of 28 weeks or more, or delivery weights of 1000 g or more. To adjust for the oversampling of fetal deaths, deflated sampling weights were attached to all observations for this research, resulting in a nationally representative sample. (Deflated sampling weights were calculated as the original sample weight times the sample size divided by the sum of weights.) The 2.3% of women who made no prenatal visits were excluded from these analyses.

Unimputed data were used from the live birth and fetal death records and from the follow-back questionnaires to the providers of prenatal care and the administrators of the hospitals where deliveries occurred. The prenatal care providers and the hospital administrators (hereafter referred to as the medical source) were asked to refer to medical records to answer detailed questionnaires about the prenatal care given to the women. The NNS and NFMS data have been described in detail elsewhere.[12,13]

Missing medical data may be due to the medical record being incomplete or invalid or it may be that the survey respondent did not fully transcribe the medical record. Donabedian argued that medical record keeping is one dimension of the quality of performance as well as the medium for evaluating other dimensions of care.[14] Also, two sources were asked to transcribe the medical information. Because of these factors, missing data were counted as missing examinations.

Variables

For the entire prenatal period, the medical sources recorded whether hematocrit and hemoglobin levels were obtained. For each prenatal visit, the medical sources recorded blood pressure and result of the urine test for protein. These data were transformed into the percentage of prenatal visits at which blood pressure was measured and the percentage of prenatal visits at which urine was checked for protein. The medical sources were also asked whether physicians advised women to restrict salt or to use diuretics during pregnancy.

The percentage of visits at which urine was tested is skewed to both ends of the range. Therefore, the variable was transformed into a dichotomous variable: whether urine was tested at no visits or at some percentage of visits greater than zero.

Table 1 lists the explanatory variables used in the analyses. The variables, "graduate" and "top visits" are indicator variables representing the top values of the "education" and "number visits" variables. "Graduate" and "top visits" were tested for an effect in each model but were only left in if they improved the model fit (Table 1).

The month of pregnancy that prenatal care was begun and the number of visits that the woman made were entered as controls in the blood test and advice models (Table 1). A provider does not expect to check hemoglobin and hematocrit levels or give particular pieces of advice more than a couple of times and may wait until

after the first visit to do so. If the woman does not return for further visits after the first, or skips the visit when the test or counseling was scheduled, she may be less likely to receive these services at all.

The maternal health status factors listed in Table 1 were included as controls in the advice models because of their possible relationship with the sociodemographic and advice variables.

Statistics

Multiple linear regression analysis as implemented on the Statistical Analysis System (SAS)[15] was done in order to determine the statistical significance of sociodemographic factors in explaining the level of blood pressure monitoring during prenatal care. Logistic regression analysis using SAS[16] was used to estimate the effect of the sociodemographic factors on the occurrence of urine testing, blood testing, and the giving of appropriate advice.

Results

Prenatal Surveillance

During 1980, nearly one third of the women who obtained prenatal care (32.8%) did not receive blood pressure examinations at all of their prenatal visits. Providers skipped all blood pressure examinations on 12.9% of prenatal care recipients (Table 2). Over three quarters of women did not have urine tests for protein at all of the visits they made. One third of prenatal care recipients had no urine tests done during prenatal visits (Table 2). Prenatal care providers obtained no blood test for hemoglobin or hematocrit on 6.6% of the women who were prenatal care recipients (Table 2).

The set of sociodemographic factors (i.e., age, education, race or ethnicity, marital status, parity, and county of residence) explains only a minimal amount of the variance in the percentage of visits at which blood pressures were taken (R^2 = .027).[17] Nonetheless, most of the sociodemographic factors are statistically significant in the regression. For each additional year of education, there is an increase of two thirds of a percent in the number of visits at which blood pressure was taken. Non-Hispanic Whites and Asians and Pacific Islanders received blood pressure exams at almost 10% more of their visits than Hispanic White women (the excluded group). Native American and Black women did not differ in a statistically significant way from Hispanic White women. Married women had blood pressures taken at 4% more of their prenatal visits than unmarried women. For each additional level of parity, women had blood pressure checked at 1% fewer of the visits they made. Finally, women living in metropolitan counties had blood pressures taken at almost 2% fewer of the visits than did women living in nonmetropolitan counties (Table 3).

Turning to the urine test regression, the model χ^2 statistic shows that the set of sociodemographic variables are useful in classifying women in the test or no-test groups ($P < .001$).[17] The maximum likelihood estimate χ^2 statistic for the individual parameters tests the hypothesis that the parameter equals zero. According to this test, women with higher education

***$P < .001$.

were more likely than women with less education to receive urine tests at their prenatal visits. This was also true for non-Hispanic Whites and Asians or Pacific Islanders relative to Hispanic Whites. Married women were more likely to be tested at visits than unmarried women. Lower parity women were more likely than high-parity women to receive urine testing. And again, nonmetropolitan dwellers were at an advantage over metropolitan dwellers (Table 4).

As shown in Table 5, the sociodemographic variables are useful in classifying women as recipients of the blood test for hemoglobin or hematocrit ($P < .001$). Of the independent factors, maternal age, a graduate education, marital status, and parity are statistically significant. The likelihood that a woman would receive a blood test increased with age, as it did for married women and women of lower parity. Women with 17 or more years of education received blood tests for hemoglobin or hematocrit significantly more often than less educated women (Table 5).

Advice Concerning Salt Restriction and Diuretics Usage

Physicians reported advising salt restriction for 34.5% of hypertensive women, 36.7% of preeclamptic women, and 13.4% of women who were free of any physician-identified complications. Fifteen percent of the overall sample were advised to restrict salt (Table 2).

As shown in Table 6, the set of sociodemographic, health status, and prenatal care factors is useful in classifying women according to the kind of advice that they received regarding salt restriction ($P < .001$). The sociodemographic attributes that decrease the log-likelihood of being advised to restrict salt are being unmarried, having higher parity, and residing in a metropolitan county.

The final logistic regression shows that the set of sociodemographic and control variables is useful in classifying women according to whether they received advice to use diuretics ($P < .001$). Physicians were less likely to advise the use of diuretics for women who had higher parity, were younger, more educated, unmarried, or living in metropolitan counties (Table 7).

Discussion

Although these data are somewhat dated, it was deemed essential to use a nationally representative sample to analyze this health policy topic. Prenatal care data from the National Maternal and Infant Health Survey, the more recent version of the NNS and NFMS, will not be available for analysis until early 1992.

These results point to the importance of including quality of care measures in examining the adequacy of prenatal care. Prenatal care is far from being of even minimally acceptable quality for many women who have made the effort to engage the prenatal care system. High proportions of women were not tested, or not regularly tested, for the basics in prenatal care: blood pressure, urine, hemoglobin, and hematocrit. The advice that many women received concerning salt restriction and the use of diuretics was not congruent with current practice.

Distribution of the tests done to monitor the health of pregnant women varied substantially according to sociodemographic factors, as did the kinds of prenatal advice given. However, the groups of women who were likely to receive poor surveillance were mainly different from the groups likely to receive poor advice. These inconsistencies mean that physicians who provided prenatal care that was of good quality in terms of basic surveillance frequently gave advice that did not follow current recommendations.

The explanation for these inconsistencies may lie in the large percentage of variation in quality that is left unexplained by these models (Table 3). The setting of the health care practice is one variable that could be important. For example, physicians practicing in academic medical centers may have been aware of and followed new advice guidelines before physicians

TABLE 7—Multiple Logistic Regression of the Advice Given by the Physician Regarding Diuretic Use on Maternal Predictors

in private practice. At the same time, those busy centers may have been settings where surveillance was missed. Without downplaying these inconsistencies, it seems best to concentrate most upon the surveillance results. The theories about optimal behavior in the areas of salt and diuretics usage had undergone recent revision in 1980. Well-qualified physicians may have known, but been unconvinced, that the recent changes in recommendations about salt and diuretics usage were sound. As pointed out by Hemminki,[1] disregarding changes in medical guidelines may in fact serve the best interests of the patient. She gives the example of x-rays, which were recommended during pregnancy and then found to be dangerous and rescinded.

The variability in quality of care according to maternal sociodemographic attributes may be explained in two ways. First, physicians allow their clinical judgment to be significantly affected by the nonmedical characteristics of the woman they are treating. Second, women of different sociodemographic backgrounds are obtaining health services from providers of substantially different quality. Although these data contain no information on the provider of prenatal care, we know that unmarried women would have higher likelihood of being on Medicaid.

Overall, the groups found to be in a relatively deprived position in terms of surveillance are already known to be the groups who obtain care later in pregnancy and in apparently inadequate quantity. It is possible that socially disadvantaged women discover early in life the low quality of the health services provided for them and decide that the costs of making visits (e.g., child care, transportation, opportunity costs of time spent) exceed the benefits.

From a policy perspective, this finding means that the prenatal care problem in this country rests as much with the quality of care delivered to disadvantaged women in particular as with this group's failure to seek the care that is available. Several approaches to the problem are apparent. We need to ascertain, first, that protocols for prenatal care at public facilities match the ACOG guidelines and, second, that these protocols are being followed by physicians and hospital staff. Third, we need to develop a quality control system for private providers. Federal and state funders of prenatal care should make quality assurance an integral part of their evaluation protocol. Finally, low reimbursement rates for prenatal care may contribute to the differences in surveillance outlined here. Providers of services to Medicaid recipients have an incentive to take shortcuts because of the low payment received for such services. Also, the training of the private providers of prenatal services to the poor may be poorer than that of providers to women with higher reimbursement potential.

On the other hand, women need information about the standard components of prenatal care. Most public education has been directed at the necessity for early prenatal care. The assumption has been that once the woman is integrated into the system, it will provide for her needs adequately. It is clear that for many women, this is an inaccurate portrayal of the situation. Basic information about the normal components of prenatal care could be incorporated in the educational campaign that promotes participation in the prenatal care system. Undoubtedly, well-informed and socially advantaged women not only choose better providers, but place demands on providers to deliver more services. Although women, especially socially disadvantaged women, cannot be expected to act as powerful enforcers of medical standards, they may at least be able to change providers if they are dissatisfied. ☐

Sixth National Conference on Chronic Disease Prevention and Control to Be Held in Washington, DC

The Centers for Disease Control, the Association of State and Territorial Health Officials, and the Association of State and Territorial Chronic Disease Program Directors are the cosponsors of the Sixth National Conference on Chronic Disease Prevention and Control entitled "Making Prevention a Reality." The conference will be held October 22 to 24, 1991, in Washington, DC, and is open to the public

The conference will emphasize interactions between federal, state, and local health departments; voluntary health agencies; and professional organizations. It will include two plenary sessions: Legislative Issues in Chronic Disease Prevention, and Community Action in Minority Communities for Achieving the Year 2000 Objectives. Concurrent sessions of invited papers will focus on the following topics:

- Use of Epidemiology for Program Decision Making
- Women's Health Issues—Cardiovascular Disease, Osteoporosis, Aging
- Breast and Cervical Cancer Control
- Behavioral Research—What Have We Learned?
- Linkages Between Academic Centers and Public Health Agencies
- State Activities in Community Chronic Disease Prevention

Additional information is available from the Center for Chronic Disease Prevention and Health Promotion Mailstop K-43, CDC, Atlanta, GA 30033 (tel: 404/488-5390 or FTS 236-5390; fax: 404/488-5962).

Effects of Paternal Occupational Exposure on Spontaneous Abortions

Marja-Liisa Lindbohm, MSc, Kari Hemminki, MD, Michèle G. Bonhomme, MSPH, Ahti Anttila, MSc, Kaarina Rantala, MSc(Eng), Pirjo Heikkilä, MSc, and Michael J. Rosenberg, MD

ABSTRACT

Background: Paternal exposure to mutagenic agents has been suggested to affect pregnancy outcome adversely.

Methods: A nationwide data base of medically diagnosed spontaneous abortions and other pregnancies and national census data was used to evaluate the effects of men's occupational exposures on risk of spontaneous abortion in 99 186 pregnancies in Finland. Census data from the years 1975 and 1980 provided information about the occupation, industry, and socioeconomic status. A job-exposure classification was developed to classify women and their husbands according to possible occupational exposures on the basis of their occupational title and industry.

Results: In 10% of the pregnancies, the husband was exposed to one or more of the mutagens, and the rate of spontaneous abortion was unaffected (OR = 1.0). Of the 25 specific mutagenic exposures evaluated, paternal exposure to four (ethylene oxide, rubber chemicals, solvents used in refineries, and solvents used in the manufacturing of rubber products) was associated with an increased relative risk of spontaneous abortion. In addition, the risk of spontaneous abortion was higher among wives of rubber products workers than among unexposed men.

Conclusions: Although there is some biological rationale for the findings of this study, these findings need to be confirmed by studies in which individual exposures can be measured directly. (*Am J Public Health*. 1991;81:1029–1033)

Introduction

In animals paternal exposure to mutagenic compounds can increase the rate of spontaneous abortions.[1] In humans, however, this relationship remains unclear. For vinyl chloride,[2] anesthetic gases,[3] dibromochloropropane,[4] chloroprene,[5] smelter work,[6] waste water exposures,[7] and organic solvents,[8] effects have been suggested, but the data either have been contradictory or remain unconfirmed. An association has also been found with some paternal occupations: metal-plate and constructional steel workers, crushers and grinders, sewers, workers caring for fur-bearing animals,[9] and mechanics and repairers of motor vehicles.[10]

Several methodologic issues must be considered in conducting studies concerning male effects on reproduction. First, such studies must take into account maternal factors. Second, they should collect data on pregnancy outcomes which minimize systematic bias. Third, they need large enough numbers of exposed men to provide reasonable statistical power. We attempted to address these issues in studying the effects of male occupational exposures on the outcome of pregnancy by using data from two national censuses and a nationwide data base of medically diagnosed pregnancy outcomes. Exposures were determined indirectly by using a job-exposure classification. This large dataset can be used to generate hypotheses for other studies of the effects of occupational exposures on reproductive outcomes.

Methods

Data on reproductive outcomes and maternal age were obtained from the nationwide Hospital Discharge Register (HDR) and from hospital clinics. We collected data on all women with a diagnosis of spontaneous abortion (ICD-8 codes 643 and 645), induced abortion (ICD-8 codes 640–642) and birth (ICD-8 codes 650–662) between 1973 and 1982. A separate questionnaire was sent to the hospitals to collect information on patients treated on an outpatient basis and not registered in the HDR. The content, technical quality, and reliability of the data base of medically diagnosed pregnancies have been described elsewhere.[11]

Information on the occupation and industry of women and their husbands and the women's socioeconomic status was obtained from the 1975 and 1980 national censuses of the Central Statistical Office of Finland. Pregnancy data for the years 1973 to 1978 were linked to the 1975 census, and the data for the years 1979 to 1982 to the 1980 census.

In the census of 1975, performed on December 31, 1975, occupational information was requested as follows: "Occupation in the place of employment" with the instruction "State your occupation as accurately as possible, not only by hon-

TABLE 1—Pregnancy Outcomes Among Wives and Adjusted[a] Odds Ratio of Spontaneous Abortion for Paternal Exposure to Mutagenic Agents

Husband's Exposure Status	Spontaneous Abortions	Induced Abortions	Births	All Pregnancies	Odds Ratio	95% Confidence Interval
Not exposed[b]	7772	7029	72 8[illegible]	87 616	1.0	
Potential, low exposure	820	1045	806[illegible]	9930	1.0	0.9 – 1.0
Moderate or high exposure	139	151	1350	1640	1.0	0.9 – 1.2

[a] Adjusted for age (≤24, 25–29, 30–34, 35–39, ≥40); socioeconomic status (1 = employers, own-account workers, upper level employees, 2 = lower level employees, students and pupils, 3 = manual workers); maternal exposure to reproductive hazards (not exposed, exposed).

[b] Referent category.

orary titles or degrees." In the census of 1980, performed on November 1, 1980, the question was, "In which occupation did you work for the longest period during the last 12 months?" Occupations were coded by census officials, on the basis of the Nordic Classification of Occupations and the International Standard Classification of Occupations. Industry was coded on the basis of the Finnish Standard Industrial Classification.

We classified the occupational exposure status of men and women on the basis of occupation and industry, using a job-exposure classification developed in cooperation with two experienced industrial hygienists. The job-exposure classification is organized by job groups, which are combinations of occupation and industry having a similar type of exposure. For each job group a list is given of agents suspected of having adverse effects on reproduction. The assessment of the exposures among the job groups was based on the industrial hygienic measurements made by the Institute of Occupational Health[12,13] and the Finnish register of employees occupationally exposed to carcinogens (ASA Register).[14]

The list of potentially dangerous agents in the classification comprises 78 exposures, including separate chemical substances (e.g., benzene, ethylene oxide), mixtures of exposures (e.g., mixtures of solvents or metals), and nonspecific exposure groups (e.g., biologic factors, rubber chemicals, pesticides). Twenty-five of the 78 exposures were suspected mutagens, based mainly on the classification of the International Agency for Research on Cancer.[15]

Three levels of exposure were distinguished according to the results of industrial hygienic measurements and the prevalence of exposure in the job group: "moderate or high," "potential, low," and "none." "Moderate or high exposure" included jobs in which the level of exposure to mutagens was continuously at least half of the Threshold Limit Value (TLV) or higher or in which the exposure periodically exceeded TLV and the prevalence of exposure was high. "Potential, low exposure" denoted either (a) jobs with low level but high prevalence of exposure to mutagens, (b) jobs which lacked industrial hygiene measurements but which were reported to the ASA Register, or (c) jobs with a high level and unknown prevalence of exposure.

The susceptible time period was determined on the basis of the time of conception and the time period for which the two censuses obtained information on occupation. For men, the time of spermatogenesis (80 days before conception) was defined as the relevant time period for exposure; for women, the relevant time period was considered to be the first trimester of pregnancy. The analysis of exposure to any mutagenic agents was limited to the pregnancies terminated between January 1, 1976, and December 31, 1976, and between May 1, 1980, and April 30, 1981. In the analysis of specific mutagenic exposures we used a 2-year period close to the census, i.e., January 1, 1976, to December 31, 1977, and May 1, 1980, to April 30, 1982, because the number of workers exposed to a specific agent was often small.

After the pregnancies of women less than 12 and more than 50 years of age had been excluded as well as those with unspecific data on men's and women's occupation, industry, or socioeconomic status, the study population included in the analysis for the limited time periods of January 1 to December 31, 1976, and May 1, 1980 to April 30, 1981, comprised 99 186 pregnancies.

The risk odds ratios comparing the odds of spontaneous abortion for paternal exposure to a mutagen with the odds of spontaneous abortion for the nonexposed group were obtained by using linear logistic regression analysis.[16] To minimize random error in the effect estimates, low and moderate or high levels of exposure were combined if the number of the workers in either category was too small. Age, socioeconomic status, and maternal exposure to potential reproductive hazards were included in the models to control for the confounding effect of these variables. To gain precision, odds ratios were only adjusted for age if fewer than 100 pregnancies occurred among the workers exposed to a chemical. The exclusion of socioeconomic status in the model did not significantly change the odds ratios for these exposures. Maximum likelihood estimates of odds ratios, which were used as surrogate measures of relative risks, and their 95% confidence intervals were calculated by using the GLIM computer program.[17] Odds ratios for exposure to mutagens were similar regardless of whether induced abortions were included or excluded from the denominator. In calculating the rate of spontaneous abortion, we included births, spontaneous abortions, and induced abortions in the denominator. (Although it is common in the literature to refer to these measures as rates, they are in fact proportions or risks because they are calculated by dividing the number of spontaneous abortions by the total number of pregnancies.[16])

Results

The rate of spontaneous abortion in the study population was 8.8%, which is nearly the same as the rate among all Finnish women (8.9%).[11] Of the husbands, 10% were considered to have low or potential occupational exposure to mutagenic agents and only 1.7% were classified as heavily exposed (Table 1). After adjusting for maternal age, socioeconomic status, and maternal exposure to reproductive hazards, the odds ratio of spontaneous abortion did not differ significantly from one for either level of paternal exposure to mutagens (Table 1).

The adjusted odds ratio was significantly increased for four paternal exposures: ethylene oxide (OR = 4.7, 95% CI 1.2-18.4), solvents used in the petroleum refineries (OR = 2.2, 95% CI 1.3-3.8), rubber chemicals (OR = 1.5, 95% CI 1.1-2.2) and a subgroup of the former, solvents used in the manufacture of rubber products (OR = 1.9, 95% CI 1.2-2.8; Table 2). Except for ethylene oxide, these exposures are mixtures of several chemicals. From the solvents used in the refineries, gasoline and benzene are suspected to be mutagens. Similarly, from the solvents used in the manufacture of rubber products 1,1,1-trichloroethane and methylene chloride are suspected mutagens. Some of these chemicals also appear in the classification as specific exposures. When paternal exposure to gasoline, benzene, and 1,1,1-trichloroethane were analyzed separately, the odds ratios did not differ significantly from unity.

TABLE 2—Adjusted[a] Odds Ratio of Spontaneous Abortion for Paternal Exposure to Specific Mutagens[b]

Exposure[c] (Level of Exposure)	Number of Spontaneous Abortions	Number of Pregnancies	Odds Ratio	95% Confidence Interval
Ethylene oxide (low)	3	10	4.7[*d]	1.2–18.4
Solvents, petroleum refineries (gasoline, benzene) (moderate or high)	16	93	2.2[**d]	1.3–3.8
Impregnents of wood (arsenic, chromium, creosotes) (low and moderate or high)	5	33	1.9[d]	0.7–5.0
Solvents, manufacture of rubber products (1,1,1-trichloroethane, methylene chloride) (low and moderate or high)	26	180	1.9[**]	1.2–2.8
Rubber chemicals (low and moderate or high)	34	280	1.5[*]	1.1–2.2
1,1,1-Trichloroethane (moderate or high)	3	24	1.5[d]	0.4–5.0
Radon (moderate or high)	26	248	1.2	0.8–1.8
Formaldehyde (formaline)				
Low exposure	110	1212	1.1	0.9–1.4
Moderate or high exposure	54	596	1.0	0.8–1.4
Polycyclic aromatic hydrocarbons				
Low exposure	1022	11 970	1.0	0.9–1.0
Moderate or high exposure	142	1619	1.0	0.9–1.2
Nickel and nickel oxides (low)	284	3371	1.0	0.9–1.1
Chromium and chromium compounds (low)	286	3444	1.0	0.9–1.1
Solvents, manufacture of plastic products (styrene) (moderate or high)	24	285	1.0	0.7–1.5
Benzene (low)	55	655	1.0	0.7–1.3
Metals (nickel, chromium, cadmium), basic metal industries and manufacture of metal products (low)	155	1603	1.0	0.8–1.1
Motor gasoline (low)	189	2381	0.9	0.8–1.1
Styrene (moderate or high)	9	120	0.9	0.5–1.8
Trichloroethylene (low and moderate or high)	5	66	0.9[d]	0.3–2.1
Plastic monomers (low)	10	158	0.8	0.4–1.4
Tetrachloroethylene (moderate or high)	3	45	0.7[d]	0.2–2.4
Solvents, manufacture of drugs (chloroform, methylene chloride) (moderate or high)	3	60	0.5[d]	0.2–1.7
Raw materials of glass (arsenic, cadmium) (low)	4	99	0.5[d]	0.2–1.3
Hydrazine (low)	2	51	0.4[d]	0.1–1.7
Solvents, manufacture of printing inks (ethene) (moderate or high)	1	33	0.3[d]	0.0–2.5
Nitroglycol, nitroglyserine, trinitrotoluene (low)	1	34	0.3[d]	0.0–2.3
Solvents, manufacture of glue and gasein (ethene) (moderate or high)	1	35	0.3[d]	0.0–2.3

[d] Adjusted for age only.

*$P < .05$, **$P < .01$

The risks of spontaneous abortions were also calculated for paternal exposure to lead, carbon disulfide, and heat, which are not mutagens but may adversely affect spermatogenesis. For all these exposures, the odds ratio was below unity but the corresponding confidence interval did not exclude one (Table 3).

In some cases, job title may be a good and specific index of a worker's exposure. For this reason, we calculated the odds ratios of spontaneous abortion by paternal occupation using the 55 occupations included in the exposure classification. The comparison group consisted of wives whose husbands were not exposed to any mutagen. Table 4 lists in descending order the paternal occupations with the highest odds ratios (> 1.20).

Only the results obtained for wives of men employed as rubber product workers reached statistical significance. At the top of the list are also two other occupations in which workers may be exposed to chemicals which we found were associated with an increased risk of abortions (Table 2). These occupations are technical nursing assistants (potentially exposed to ethylene oxide) and oil refinery workers (potentially exposed to solvents of oil manufacture). Other occupations with a high risk of abortion were watchmakers and chimney sweeps.

Discussion

Paternal exposure to certain mutagens may induce spontaneous abortions. We found no difference in the risk of spontaneous abortion between wives of men exposed to any mutagen and wives of men exposed to no mutagen. This may suggest that only a subgroup of mutagens induce spontaneous abortions. Moreover, the mutagenicity of some of the classified agents, such as 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, chloroform, methylene chloride, and the

metals as a group is not well established and depends on the mutation assay used. Thus mutagenicity of the agents such as these is debatable.[15,18] Another example of lack of effect is paternal smoking, one of the most common mutagenic exposures, which appears to have no effect on fertility (time to pregnancy).[19,20]

Of the 25 specific mutagens or groups of mutagens evaluated in this study, paternal exposure to the following four was associated with an increased risk of spontaneous abortion: ethylene oxide, rubber chemicals, solvents used in petroleum refineries, and solvents used in the manufacture of rubber products. Among these, ethylene oxide has been identified as a mutagen by almost all mutation assays, including the dominant lethal assay.[15] Exposure to this chemical has also been associated with spontaneous abortion in women who use the chemical to sterilize hospital instruments.[21] However, our finding of the effects of ethylene oxide is based on a small group of exposed workers. In addition, the job group to which exposure to ethylene oxide was attributed is heterogeneous, and no individual exposures could be confirmed. Rubber chemicals contain several microbial mutagens,[22] and an increased risk of abortion has been observed among women exposed to rubber chemicals.[23] An excessive rate of spontaneous abortion has been found among the wives of workers in a waste water treatment plant of a petroleum refinery[7] and among the wives of workers exposed to organic solvents.[8]

Analyses by occupational title identified only 1 out of 55 occupations, rubber workers, for which the wife's risk of spontaneous abortions was higher than that of wives of men not exposed to mutagens. The wives of men exposed to potentially spermatotoxic but nonmutagenic agents, such as lead, carbon disulfide and heat, did not appear to have an increased risk of spontaneous abortions.

Genetic damage to male germ cells is the only mechanism of male-mediated effects on pregnancy outcome for which supporting evidence is available.[24] Another potential mechanism could be that harmful substances are transmitted to the pregnant woman by contact with clothes or by semen leading to secondary maternal exposure. We were unable to separate the effects of these two routes of exposure.

The misclassification of exposure and pregnancy outcome is an important source of bias in studies of occupational exposure and reproductive outcomes. In this study, misclassification of pregnancy outcome was likely to be small because the data were obtained from hospital records, and spontaneous abortions were medically diagnosed. These data were therefore less susceptible to the information bias which might arise from self-reported data on pregnancy outcome.[11]

In Finland induced abortions are legal. If any induced abortions are reported as spontaneous abortions, we would expect this misclassification to be very small.

It is certain that early spontaneous abortions and a small percentage of induced abortions were not included. The duration of pregnancy before a spontaneous abortion may vary by paternal exposure status. If early fetal losses, which were not included in the study, occurred more often among wives of men exposed to mutagens, the odds ratios reported would underestimate the true relative risk. If the converse were true, the odds ratios would overestimate the true relative risk.

The weaknesses of the study pertain to the potential misclassification of exposure status. Assignment of exposure status was made on the basis of occupational titles and industry. In some cases, these data may not have been sufficiently specific to assess exposure status accurately. Consequently, some exposed persons may have been classified incorrectly as unexposed, and this could have resulted in low sensitivity of the exposure assessment. Conversely, occupational categories may have been so broad that unexposed persons may have been classified as exposed, inducing low specificity. Random error in the classification of exposure status (nondifferential misclassification) may have diluted the effects of exposures and may explain the absence of associations in this study.

Although census data do not provide completely accurate exposure information, care was taken to assess exposure as accurately as possible. First, analyses were carried out in the time period close to the date of the censuses to allow minimal time for change in occupation. Second, exposure status was determined independently of reproductive outcome. Third, the job exposure classification rather than mere job title was used to assign exposure status; in some cases it was possible to quantify the exposure.

No information was available on other potential confounding factors such as previous spontaneous abortions or the use of alcohol or smoking. Probably the adjustment of the socioeconomic status has partly controlled the effect of smoking and alcohol drinking, as they vary by social class.

This large study showed no overall excess of spontaneous abortions in women whose husbands were exposed to mutagens in general compared with those whose husbands were not exposed to mutagens. However, excesses were observed among wives of men employed as rubber products workers and of men exposed to ethylene oxide, solvents used in petroleum refineries, rubber chemicals, and solvents used in the manufacturing of rubber products. Many comparisons were made in this study, and some of the associations probably reflect chance alone. Thus, our findings are only suggestive. This emphasizes the need to base inferences on biologic plausibility and on the evidence accumulated from this and other studies. Although there is some biological rationale for these findings, they need to be confirmed by studies in which individual exposures can be assessed directly. ☐

Acknowledgments

This project was funded in part by Family Health International under a cooperative agreement with the United States Agency for International Development. However, the views expressed in this article do not necessarily reflect those of the funding agency. Family Health International is an international not-for-profit organization which conducts research and provides technical assistance in health, family planning, sexually transmitted diseases, and AIDS.

The Health Hazards of Saunas and Spas and How to Minimize Them

Edward Press, MD, MPH

ABSTRACT

Background: The rapidly increasing number of spas, hot tubs, and saunas intensifies the potentials for deaths from hyperthermia and drowning.

Methods: I analyzed 54 such deaths reported to me by 55 medical examiners and coroners in the United States and 104 deaths reported to the US Consumer Product Safety Commission (CPSC).

Results: Only seven of the 158 deaths analyzed occurred in saunas. All of the remaining deaths occurred in spas, jacuzzis, or hot tubs, which were far more numerous. The chief risk factors identified were alcohol ingestion, heart disease, seizure disorders, and cocaine ingestion (alone or in combination with alcohol ingestion). These factors accounted for 71 or 44.7% of the 159 fatalities. Of these risk factors, alcohol represented 38%; heart disease, 31%; seizure disorders, 17%; and cocaine ingestion, alone or in combination with alcohol, 14%. Sixty-one of the 151 spa-associated deaths occurred in children under 12 years of age. Accidental drownings from uncovered or improperly covered spas and,to a lesser extent, entrapment by suction, were the chief causes of childhood drownings.

Conclusions: Children and older persons who have heart disease or seizure disorders or who use alcohol or cocaine are especially vulnerable. Recommended preventive measures include shortening the time of exposure, lowering the temperature, establishing safety standards for covers and for baffles for suction outlets, and using warning notices. (*Am J Public Health.* 1991;81:1034–1037)

Introduction

The "dry" or Finnish Sauna is an enclosure large enough for two to eight or more persons; it generally has no active ventilation, is heated by electricity, gas, or other means; temperatures are maintained at 70°C to 90°C, but often can be raised up to 100°C. Spas are large bath tubs or small pools made of synthetic materials; they have equipment that heats, recirculates, and disinfects the water and usually has jets of water or air or both. Hot tubs are similar to spas, but they are made of wood and their recirculating water may or may not have jets of water or air. The water in both spas and hot tubs is heated to about 40°C, but may go even higher. Health hazards from hot tubs are similar to those from spas. In this article the term "spas" includes hot tubs, but does not include the smaller jetted bath tubs that are emptied after each use.

The exact number of saunas in the United States is not known. The Sauna Society of America estimates the number at about 1 million (personal communication from V.S. Choslowsky, President, Sauna Society of America, Sept. 1988). More accurate estimates are available for spas and hot tubs; one of the trade associations placed the number at about 1.8 million in 1988 (personal communication from Larry E. Paulick, Sr., vice-president, National Spa and Pool Institute, Alexandria, Va, Dec. 5, 1988). A trade publication placed the number that are sold annually at 250 000 (personal communication from Kathleen Bedenbaugh, editor, Aqua Magazine, Harcourt-Brace Jovanovich Publications, Santa Anna, Ca, Oct. 1988. Thus there would be millions of monthly exposures to the hazards of hyperthermia and drowning. To reduce the risks from these exposures, voluntary standards have been developed by several organizations. One of these, Underwriters Laboratories' Standard 875 for Electric Saunas requires the use of the following warning sign: "Do not exceed 30 minutes in sauna. Persons with poor health should consult physician before using sauna." Because (as noted below) a 30-minute exposure has been found to be unsafe for some persons, and because there is so little information available on mortality in saunas and spas in the United States, I undertook a literature review and then attempted to collect information on deaths associated with spas and saunas.

Literature Review

According to Kauppinen and Vuori,[1] warmth induces a feeling of euphoria, relaxation, and tranquility in many persons. Sorri discussed saunas in a regular issue of the Annals of Clinical Research[2] and in a special issue of the same journal,[3] which includes two editorials and 16 articles on the Finnish sauna. The author states that bathing in a sauna is a pleasant and relaxing experience, which combines psychic, physical, and social pleasures; reduces aggressive behavior; and enables bathers to forget the common pressures of everyday life. He also feels that the nature of the experience makes it difficult to define objective scientific methods of measurement.

This paper was submitted to the journal February 27, 1990, and accepted with revisions February 19, 1991.

The increased pressure from the water results in peripheral vasodilation, profuse perspiration with a decrease in the extracellular blood volume, an increased viscosity of the blood, an increase in hematocrit with shortened clotting time, and a 20% increase in the consumption of oxygen.[1] The electrocardiographic (ECG) changes include a T-wave depression, ventricular and supraventricular extrasystoles, and a deep S wave.[4] Thus the possibility of cardiac arrest exists. This would be especially true for persons with preexisting heart disease or those on medications that influence cardiac rhythms. The combination of peripheral vasodilation and decreased blood volume from the loss of fluids reduces the cerebral blood flow and increases the likelihood of syncope. Three out of 60 subjects using a Finnish Sauna for 20 minutes at a temperature of 80°C to 90°C fainted; a fourth, a 63-year-old, apparently healthy, man, developed an angina attack; his ECG tracings showed ventricular and extraventricular extrasystoles, which persisted for a half hour after he left the sauna.[4] Jokinen et al.[5] studying children found that of 61 children that had a 10-minute exposure in a sauna, two developed vasovagal collapses.

Diabetics receiving subcutaneous injections of insulin may absorb their insulin much more rapidly because of the peripheral vasodilation. Khogali and Gales[6] feel that "it is quite common for patients with heat stroke to have diabetes, as though they are predisposed. . . . Since diabetics often exhibit postural hypotension due to faulty baroreflexes it is conceivable that this could be responsible for the relatively poor adjustments in vasculature of various body regions." Sweating abnormalities and neuropathy of the autonomic nervous system also are common to diabetics. Hormonal activity resulting in increased secretions of catecholamines and an increased sympathomimetic activity have been reported.

Because in the sauna and spa the testicles, which are normally below internal body temperature, are exposed to temperatures well above normal body temperature, the possibility of impaired spermatogenesis exists. B. J. Procope, as quoted by Kauppinen and Vuori[1] stated that intensive sauna bathing, repeated six to eight times within a 2-week period, caused a reduction in the number of sperm cells in 12 medical students accustomed to the sauna. Brown-Woodman, also quoted by Kauppinen and Vuori, reported that even a single 20-minute exposure to a sauna at 80°C decreased the number of sperm cells starting 1 week after the bathing and lasting for 5 weeks. He found that there were no changes in the morphology; but ultrastructural changes of the sperm cell were observed.

Questions of potential teratologic effects on the developing fetus when pregnant women are exposed to the hyperthermia of the sauna and the possibility that such exposure might induce labor prematurely in women approaching full term, have also been raised. Edwards[7] in a fairly extensive review of the clinical significance of experimental studies on hyperthermia as a teratogen, found that "the species known to be affected include birds, all the common laboratory animals, farm animals, and primates. It would be remarkable if it were not also a human teratogen." He concluded that because there is very strong evidence that hyperthermia is a human teratogen more study is required to fully determine the nature and extent of this risk to prenatal development. He thought that an elevation of 1.5°C to 2.5°C above the species' normal temperature could result in a heat-induced teratogenic effect.

Vaha-Eskeli and Erkkola[8] after reviewing some of the literature and testing 23 pregnant women, concluded that at least, as practiced in Finland, hyperthermia was not teratogenic. The authors did, however, comment that in Finland it is commonly believed that sauna bathing could be used to induce labor in postterm women. In their study of the effect of thermal stress on 23 women who were 36 weeks pregnant, they found that 5 of the women had occasional uterine contractions, although 1 of the 5 experienced the contractions before, as well as after, the sauna exposure.

Method

After a preliminary telephone poll of 16 US medical examiners and coroners, a questionnaire (available from the author) requesting information on the number and type of deaths associated with saunas, spas, and hot tubs and related risk factors noted during the past 5 years was sent to 184 members of the National Association of Medical Examiners. The members were selected on a subjective basis from the entire list of 654 members. When several different members were from the same office, the chief or director, rather than deputies, assistants, or consulting pathologists was chosen. In addition, wide geographic distribution coupled with representation from urban and rural areas and from hot and cold climates were factors in the selection. To supplement these factors, a medical examiner who was a longtime member of the association and familiar with many of its members personally chose about 10 or 12 whom he considered experienced and well trained.

A total of 55 responses were received. These were followed up by telephone interviews with 20 of the 55 for more complete and detailed information. Thirty-two of the 55 respondents indicated that they could remember no fatalities during the preceding 5 years (from November 1988).

The Consumer Product Safety Commission (CPSC) has a program called the Medical Examiners and Coroners Alert Program asking medical examiners and coroners to report deaths to the CPSC. Reports of such deaths in saunas and spas were obtained from the CPSC for the period of January 1, 1986 to November 4, 1988. The reports did not include all states in the United States for the entire period, nor did those reporting necessarily include all cases in their jurisdiction.

Results

Age distribution. Only 15% of the deaths reported in my survey (all in spas), were in children under 12 years of age, compared with 52% reported to the CPSC (Table 1). This discrepancy could reflect the fact that the reports to the CPSC were more recent, most of them prepared in 1987 and 1988 when a larger number of spas were sold to private residences than to public facilities and athletic clubs, which are much less likely to have children present. The author's poll went back 5 years from 1988 when the number of private spas was lower.

Duration of exposure. Ten of the 24 jurisdictions reporting fatalities in my survey recorded the length of exposure to the spa prior to death. In four cases the exposure was more than 30 minutes; in four more, it was 10 to 20 minutes; and in two it was less than 10 minutes.

Risk Factors. Risk factors were reported in 45% of the deaths (Table 2). Alcohol ingestion and heart disease were the chief factors associated with the fatalities. Seizure disorders and cocaine ingestion either alone, or cocaine combined with alcohol, accounted for additional risk factors. In many deaths the presence or absence of risk factors was either unknown or unrecorded.

TABLE 2—Risk Factors Reported as Associated with Spa and Sauna Deaths

	SPAS CPSC[a]	SPAS[b]	SAUNAS[b]	TOTAL
Alcohol	10	15	2	27
Heart Disease	10	8	4	22
Seizures	6	6		12
Cocaine	1	2		3
Cocaine & alcohol	3	4		7
Total Reported	30	35	6	71 (44.65%)[c]

[a] Consumer Product Safety Commission's death certificate reports from their Medical Examiners and Coroners Alert Program. In only 50 of the 104 deaths were the risk factors checked as present or unknown. In the others, no mention was made of them.

[b] Author's poll of 55 medical examiners or coroners. In this poll, obesity was recorded in association with heart disease or alcohol in 8 cases.

[c] $\frac{71}{104+55} \times 100 = 44.65\%$

Discussion

The chief physiological differences between spas and saunas relate to the more rapid transfer of heat from water than from air. The jet currents in the spa further enhance the heat transfer and the evaporative cooling effects of perspiration that occur in the dry sauna do not occur when most of the body is under water in spas. Although the transfer of heat is more rapid in spas than in saunas, the gradient of heat is less. Water in spas is generally not above 40°C, which is in contrast to the 80°C or 90°C temperature of the Finnish sauna or the 50°C temperature of the steam room or Japanese sauna.

In addition to the problems of hyperthermia the hazard of drowning exists in spas. Infants can accidentally fall into the spa and drown when the spa is not adequately covered; or older children can become entrapped if the powerful outflow suction is not properly shielded. As noted in Table 2, over half of the 104 deaths reported to the CPSC were in children under 12 years of age. Shinaberger et al.[9] in a study of 74 deaths of young children in California spas found that the major factors involved were lack of supervision, access to the spas, neuromotor handicaps, and entrapment by suction.

Syncope is a hazard for adults. Hyperthermia may induce syncope, particularly in persons with heart disease or alcohol or drug ingestion. Even without these factors, staying in the spa too long or allowing the temperature to rise beyond safe limits can cause syncope.

The greater likelihood of narrowed arteriosclerotic blood vessels in the heart and brain of the elderly poses a risk, especially if they are perspiring profusely and, as a result, become dehydrated and have increased blood viscosity. Alcohol or cocaine, medications that affect the heart or the temperature-regulating mechanism or that result in drowsiness are more likely to be present in adults. Trying to sober up or counter a hangover by "sweating it out" can be a perilous activity. Ylikhari et al.[10] noted that in Finland, which has a population of 4.8 million, the consumption of alcohol has been estimated to be a contributing factor in 20 to 25 sauna-related deaths each year. He felt that alcohol intoxication and particularly the hangover phase exposes a person to cardiac arrhythmias and that the sauna may further increase the arrhythmia risk because of enhanced adrenergic activity.

The length of stay in a sauna or spa is important. The heating switch on some electrically heated saunas is set to go off automatically after 30 minutes, and one of the standards (currently under revision) cautions against exceeding 30 minutes. However, Sohar et al.[4] found even 20 minutes to be too long for 4 of his 60 subjects as noted above. The New York City Health Department requires posting a notice in public saunas, steam rooms, and spas with the following warning: "Use . . . should not exceed 15 minutes. Excessive exposure can be harmful to health" (personal communication, November 1987, between the commissioner of the New York City Health Department and the chair of the CPSC). The president of the Institute for Health Promotion Research in Finland who has done research and had an unusually extensive experience with saunas stated that "—even 10 minutes may be too long a sauna exposure for some individuals." In 2 of the 10 fatalities in the author's survey where the time was recorded the time was less than 10 minutes. Studies to determine how long pregnant women can safely remain in a spa found that the length of time varied with the temperature of the water.[11] However, using 38.9°C as a potentially teratogenic temperature, Harvey et al.[11] found that in a hot tub with water at 39°C it took the women 15 to 25 minutes (mean 23.0 minutes) to reach a body temperature of 38.9°C. When the water temperature was 41.1°C it took the women 10 to 30 minutes (mean 18.5 minutes). In a sauna at 81.4°C all 20 women felt sufficient discomfort (dizziness, tingling in hands, rapid pulse, irregular heart beat, and stomach pain) to leave before their temperature rose to 38.9°C. The subjects in the 39°C hot tubs began to leave because of discomfort after 10 minutes; those in the 41.1°C tub left after 5 minutes. Those who elected to remain because they did not experience any discomfort required the above noted times to have their temperatures reach 38.9°C.

Spas, sometimes marketed through discount stores at cut rates are often purchased by families with small children. The combination of inadequately supervised children and the use of cheaper models with substandard covers and poorly shielded suction outlets could result in accidental drowning. Mandatory, rather than voluntary, safety standards for covers and baffles might decrease this hazard. Many of the standards developed by several organizations need to be revised, and for all compliance is now voluntary. Standards have been formulated by Underwriters Laboratories[12] and the National Spa and Pool Institute.[13] The Centers for Disease Control of the US Department of Health and Human Services has also published some recommended health and safety guidelines for public spas and hot tubs.[14] A few state or local jurisdictions have adopted some of these standards (with or without recent revisions) as requirements for public facilities; they may also enforce them. However, most official agencies have taken no action. Moreover, the current mandatory standards of most official agencies cover only public and not private residential facilities. The CPSC has the authority and responsibility to promulgate mandatory standards for both public and private saunas and spas but, as of December 1990, has not done so.

Both the author's survey and the CPSC data suffer from incomplete information: the total population at risk, total number of associated deaths, and the number, type and frequency of use are not known. The sparse response rate to my survey as well as its lack of complete coverage means that many deaths and many risk factors may have been overlooked. A more thorough and complete study is needed, preferably a prospective one, to obtain a more accurate and complete picture of the problem.

Nevertheless, even the limited data presented here suggest that a public health problem exists and that the problem can be corrected through appropriate actions by the CPSC and official health agencies.

Persons with heart disease, hypertension, seizure disorders, diabetes, or significant obesity; persons who have ingested alcohol, narcotic drugs, or medications that can result in drowsiness or interfere with the body's temperature-regulating mechanism; or persons who are over 65 years of age must limit their stays in saunas or spas to 5 or at the most 10 minutes at a time. Similar precautions should be observed by women in the first trimester of pregnancy. Even healthy adults would be well advised not to stay in for more than 10 to 15 minutes at a time.

Automatic controls, limiting air and water temperatures to 80°C for the Finnish Sauna, 50°C for the steam room, and 40°C for the water temperature in the spas should be required as should effective covers for spas and proper baffles or shields for suction outlets. ☐

Serum Total Cholesterol: HDL Cholesterol Ratios in US White and Black Adults by Selected Demographic and Socioeconomic Variables (HANES II)

Shai Linn, MD, DrPH, Robinson Fulwood, MSPH, Margaret Carroll, MSPH, J. Gerald Brook, MD, Clifford Johnson, MSPH, William D. Kalsbeek, PhD, and Basil M. Rifkind, MD

ABSTRACT

Background: **Framingham Study findings suggest that total cholesterol (TC):High density lipoprotein cholesterol (HDL-C) ratio is a useful summary of the joint contribution of TC and HDL-C to coronary heart disease (CHD) risk. Information on the distribution of TC:HDL-C in the US population is limited to selected populations and the relationship of the ratio distribution and its correlates has received little attention.**

Method: **TC/HDL-C ratios were examined in a representative sample of the United States adult population ages 20 to 74 years, between February 1976 and February 1980 during NHANES II, using stratification and multivariate regression analyses.**

Results: **Age-adjusted mean ratios were higher in men compared with women and were higher in Whites compared with Blacks. White men had the highest TC/HDL-C mean ratios. These relationships remained after stratification by age, education, body mass index, alcohol use, cigarette smoking, and physical activity. Using multivariate analyses, the ratios were positively related to BMI, age, and smoking; and negatively related to female sex, alcohol use, being Black, and physical activity.**

Conclusions: **Using a ratio reference point of greater than or equal to 4.5 from the Framingham study, at least an estimated 44 million persons ages 25 to 74 years in the US were found to be at higher risk of developing coronary heart disease. (*Am J Public Health*. 1991;81:1038–1043)**

Introduction

The various cholesterol-carrying lipoproteins are independent predictors of coronary heart disease (CHD) risk. Plasma total cholesterol (TC) and low density lipoprotein cholesterol (LDL-C) levels are positively correlated with CHD, whereas high density lipoprotein cholesterol (HDL-C) levels are inversely related.[1] However, TC or LDL-C and HDL-C are poorly correlated with each other so that knowledge of both may be important to predict CHD risk than does either of them alone.

Various ratios combining TC or LDL-C and HDL-C have been introduced. Framingham Study findings suggest that TC:HDL-C ratio is a useful summary of the joint contribution of TC and HDL-C to CHD risk.[1–3]

Other summary measures, using LDL-C, may need calculations or special laboratory methods. We have chosen to report the TC:HDL-C to allow comparison with the Framingham data, since it is the main source of information on the relationship of a summary measure of TC and HDL-C with CHD mortality. This ratio has the advantage of being available to the physician and is easier to comprehend at the clinical level.

Information on the distribution of TC:HDL-C (or its inverse) in the United States population is limited to selected populations. Both the Framingham Study[1,3] and the Lipid Research Clinics (LRC) Prevalence Study[4] were not planned to be representative of the US population. Furthermore, the relationship of the ratio distribution and its correlates has received little attention.

The second National Health and Nutrition Examination Survey (NHANES II),[5,6] measured TC and HDL-C levels in a probability sample of the civilian, noninstitutionalized population of the United States and thus provides information on the distribution of the TC:HDL-C ratio for categories of selected potential correlates, namely age, sex, race, education, body mass index (BMI), alcohol intake, smoking, and physical activity.

Methods

The NHANES II, conducted between February 1976 and February 1980 by the National Center for Health Statistics (NCHS), was a national cross-sectional probability survey of the civilian noninstitutionalized population of the United States aged 6 months to 74 years including Alaska and Hawaii.[5,6] It consisted of household interviews, as well as physical examination and interviews in mobile examination centers. The household interview collected socioeconomic

This paper, submitted to the Journal April 30, 1990, was revised and accepted for publication January 23, 1991.

and demographic information on the sample person and the family and a medical history questionnaire. The medical examination was conducted according to a standardized protocol and included laboratory tests on whole blood and sera. For each person examined, dietary data including alcohol consumption were obtained by means of a 24-hour recall and a three-month food frequency questionnaire administered by trained dietary interviewers.

The three sources of nonresponse and response rates by sex and race are shown in Table 1. An analysis of selected health variables of persons who were examined versus those who were not examined (but interviewed) indicated no substantial bias due to nonresponse.[7] An examination of the characteristics of persons with and without HDL-C determinations such as age, education, BMI, alcohol use, smoking, and physical activity did not detect differences that would suggest a bias in the results. Adjustments have been made according to the usual NCHS methods so that the results reported here reflect a nationally representative sample.[5]

TABLE 1—NHANES Study population: Numbers and response rates by sex and race

		Men		Women	
	Total*	White	Black	White	Black
Total sample	17058	7059	852	8044	1103

Response rate (%)	82.7	82.3	76.1	84.2	79.7
Overall response Rate (%)	56.4	56.9	54.2	56.7	52.7

*Includes only Whites and Blacks aged 20–74 years.

Determination of Serum Lipids

Chemical analyses were provided by the LRC Laboratory at the George Washington University, and the editing and data processing were provided by the LRC Central Processing Unit, Department of Biostatistics, at the University of North Carolina. The laboratory techniques have been described elsewhere.[5,8]

Definitions

Educational level: Measured by the highest grade attended in a public or a private school.

Body mass index (BMI, Quetelet index): Weight (Kg)/height (m)}**2.

Frequency of alcohol consumption: Participants were asked about the usual consumption of alcoholic beverages during the three months that preceded the interview. Consumption was classified as follows: none (never), less than once/week (seldom), 1 to 6 times/week (weekly), or 1 or more times/day (daily). The data for all types of alcohol—beer, wine, and liquor—were compared. The greatest frequency of reported alcohol use was calculated as a composite measure of habitual (chronic) frequency of alcohol use of any kind.

Smoking: Interviewers were asked: 1) whether they had ever smoked at least 100 cigarettes during their entire life; 2) whether they currently smoked; and 3) the daily number of cigarettes smoked. Individuals who responded positively to questions #1 and #2 were defined as "current smokers." Those who responded positively to question #1 but negatively to question #2 were defined as "past smokers," and those who responded negatively to question #1 were defined as "nonsmokers." For current smokers, the data were dichotomized into those who smoked fewer than 21 cigarettes per day, and those who smoked 21 or more cigarettes per day.

Physical activity: Interviewees were asked: 1) whether they were getting "much exercise," "moderate exercise," or "little or no exercise" for recreation; 2) whether in their usual day, aside from recreation, they were "very active," "moderately active," or "quite inactive." The higher category of activity, at any time was then calculated as a composite of activity of any kind.

Statistical Methods

All statistical analyses incorporated both the weights and the complex sample design of the NHANES II. Age-specific and age-adjusted mean HDL-C levels of men and women by race and by selected correlates were estimated by use of the programs SURREGR[9] and GENCAT.[10,11] The age-adjusted means were standardized by the direct method to the 1980 US census population. The first level of analysis consisted of testing the equality in age-specific mean and the age-adjusted mean ratio by selected correlates for the four sex-race groups. Hypotheses of no difference in mean ratio were tested at the 0.05 level of significance, using a chi-square statistic with one degree of freedom. For this report the use of the word "significant" implies "statistically significant."

Second, Pearson correlation coefficients were estimated to investigate the relationship between the ratio and continuous variables such as age, years of education, and the number of cigarettes currently smoked. Correlation coefficients and standard errors were estimated by use of the program OSIRIS.[12] Since the sampling distribution of the correlation coefficients is not normal, Fisher's Z transformation of the correlation coefficients was used to test the hypothesis of zero correlation.

Third, using the SURREGR program, weighted least squares multiple regression analyses,[9] with ratio as the dependent variable, were applied to control for potential confounding. All correlates were included simultaneously in the equation.

Results

The mean ratios and selected percentiles by age, sex, and race are presented in Table 2. The ratios were directly related to age ($P < 0.001$) with Pearson correlation coefficients of 0.235 for White men, 0.207 for Black men, 0.301 for White women, and 0.247 for Black women. White men had the highest mean ratios, consistently increasing from 4.11 at ages 20 to 24 to a peak of 5.55 at ages 45 to 54, and declining thereafter.

The ratios for White men were consistently and significantly higher than those of White women. The age-adjusted sex difference for Whites was 0.77 (18 percent higher for males). Black men had higher ratios than Black women at ages 25 to 54, but Black women had higher ratios in the youngest age group 20 to 24 and at age 55 and above. Blacks had consistently lower ratios than Whites, for both men and women. All differences for men were significant.

[1] Age-adjusted by direct method to the 1980 U.S. Census Population.

+Sample size is inadequate to produce a reliable estimate.

TC:HDL-C by Categories of Correlates

Education: In Whites, there was a slight initial increase in the ratios from the first to the second category of education, and a consistent decline thereafter. However, for Black men there was a decrease in the ratio from the first to the second level of education, and a consistent increase with higher education. There was no clear trend in the ratio for Black women. The correlation coefficients were negative in all four sex-race groups, suggesting an inverse relationship between education and the ratio (data available on request from authors).

BMI: The ratios increased uniformly in all four sex-race groups with increasing BMI (Table 3). The relationships of the ratio with BMI were stronger in women than in men, and in Blacks than in Whites.

Alcohol: The age-adjusted mean of Whites of both sexes and of Black women decreased consistently with increased frequency of alcohol consumption (Table 4). The ratio of Black men was highest for those who seldom consumed alcohol and decreased consistently thereafter. For each of the four sex-race groups except for Black men there were lower ratios with increasing reported quantities of alcohol consumed over the last 24 hours. The Pearson correlation coefficients were stronger in men than in women and in Whites than in Blacks.

Smoking: In all groups with the exception of Black men, nonsmokers had lower ratios than smokers (Table 5). However, Black men who never smoked and past smokers had higher ratios than light smokers. Among the smokers, the heavier the smoking the higher the ratio in all groups with the exception of Black females, where the number of cases was too small to produce a reliable estimate.

Physical activity: White men and women, and Black men and women had the lowest ratios with highest level of reported physical activity (Table 6).

TC:HDL-C Ratio in the Four Sex-Ratio Groups after Stratification for Correlates

Sex and race patterns remained basically similar to the findings in the basic data even after controlling for correlates: Of the four sex-race groups, White men consistently had the highest ratios; and Black women had the lowest ratios after stratification for BMI and alcohol consumption (data available on request from authors).

Multivariate Analyses

In the multivariate model with all correlates (Table 7), BMI, age, and current smoking were positively and independently related to the ratio. Being female, frequent alcohol use, being Black, and physical activity were negatively and independently related to the ratio. In this model, education was not strongly related to the ratio. Similar results were obtained when the natural log of the ratio was used as a dependent variable.

Discussion

The present report provides estimates of the distribution of the TC:HDL-C ratio and the relationship to selected correlates in a representative sample of the United States population. The ratios were found to increase with age in men and women of both races. The ratios were consistently higher for men compared to women for the two races; and Whites had higher ratios compared to Blacks. These relationships remained even after stratification for categories of correlates.

The age and sex trends of the TC:HDL-C ratios were similar to those seen in the Framingham study which, however, found higher values. The socioeconomic status (SES) of the Framingham population is higher than that of the general US population. However, since higher SES was found to be related to lower ratios in the present study, SES does not account for the differences observed in the two studies. Laboratory and other methodological differences in lipids and lipoprotein determinations could account for some of the differences. A bias in the determination of lipid levels in NHANES II seems to be unlikely. All TC and HDL-C determinations were performed using a standardized procedure, without knowing the participants demographic characteristics and the quality of the laboratory determinations were routinely evaluated.

In the univariate analyses the ratio was negatively related to years of education in the four sex-race groups but when other correlates were considered in a multivariate model, the ratio was only weakly positive and weakly related to education.

TABLE 3—Age-Adjusted Mean Ratio of Total Cholesterol to HDL Cholesterol of Adults, Ages 20–74 Years, by Race, Sex, and Quartiles of Body Mass Index (BMI), and Pearson Correlation Coefficient, United States, 1976–80

Men Quartiles of BMI	*White*	*Black*
Less than 22.7	4.45	3.59
22.7–24.9	4.86	4.07
25.0–27.5	5.25	4.65

TABLE 4—Age-Adjusted Mean Ratio of Total Cholesterol to HDL Cholesterol of Adults, Ages 20–74 Years, by Race, Sex, and Frequency of Consumption of Alcoholic Beverages, United States, 1976–80

Frequency of Consumption	White Men	Black Men	White Women	Black Women
Never	5.42	4.44	4.51	4.30
Seldom	5.20	4.65	4.32	4.19
Weekly	4.92	4.19	4.05	3.76
Daily	4.74	3.77	3.63	3.53

Age-adjusted by direct method to the 1980 US Census population.
Frequency of consumption of alcoholic beverage was determined by taking the maximum reported consumption of either beer, wine, or liquor from the food frequency questionnaire.

TABLE 5—Age-Adjusted Mean Ratio of Total Cholesterol to HDL Cholesterol of Adults, Ages 20–74 Years, by Race, Sex, and Smoking Status, and Pearson Correlation Coefficient, United States, 1976–80

Smoking Status	White Men	Black Men	White Women	Black Women
Nonsmokers	4.97	4.46	4.19	4.03
Past smokers	4.99	4.51	4.12	4.21
Smokers				
1–20 cigarettes/day	5.05	4.01	4.45	4.17
21 cigarettes or more/day	5.38	4.54	4.53	—
Pearson Correlation	0.141*	—	0.049	—

Age-adjusted by direct method to the 1980 US Census population.
A past-smoker is defined as a person who had smoked at least 100 cigarettes but does not currently smoke; a nonsmoker did not smoke 100 cigarettes in his lifetime and does not currently smoke.
*P < 0.001.
—Sample size is inadequate to produce a reliable estimate.

Some limitations on the use and interpretation of the ratio may be advised. It is important to emphasize that the TC:HDL-C can change as a function of either TC or HDL-C. Furthermore, the relationship to correlates is complicated by the fact that at any given ratio level a number of correlates can influence infinite combinations of TC and HDL-C and be responsible for the final outcome. Some correlates such as age will have their effect via TC since there is no strong relationship between age and HDL-C. Conversely, alcohol consumption, for

[c] $P < 0.05$.

example, will predominantly affect HDL-C. BMI on the other hand is known to influence both components of the ratio, and indeed proved to be the most important predictor of TC:HDL-C in the multivariate analyses. Several publications have investigated the relationships of TC or HDL-C to demographic and socioeconomic variables in the US.[5,13–15] When assessing the distribution of the ratio and its correlates, these factors must be taken into consideration.

In the Framingham Study, the TC:HDL-C ratio was found to be an excellent predictor of CHD risk. Men and women who did not develop CHD within the years of follow-up had an average ratio of 5.2. For those who did develop CHD over the same period, the average ratio for men was 5.8 and for women 5.3. The American Heart Association guidelines suggest that to consider all those at or above ratios of 4.5 be considered at higher risk of CHD[1,16] as TC:HDL-C ratio of 4.4 corresponds to total cholesterol level of 200 mg/dl and HDL-C of 45 mg/dl. Using this single reference ratio, Castelli[1] estimated that 50 percent of the women and 75 percent of the men in the United States are at risk of CHD. Better estimates may be obtained using the NHANES II data (Table 2). Thus, 50 percent of the White males and at least 25 percent of the Black males ages 25 and above have ratios at or above 4.5 and would be considered at increased risk of CHD. This corresponds to population estimates of 23,877,500 White males and 1,264,500 Black males. Similarly, at least 25 percent of women, of both races, ages 25 and above would be at higher risk, corresponding to population estimates of 17,326,750 White women and 1,568,750 Black women, respectively. Thus, there are about 44 million White and Black persons in the US ages 25 to 74 who may be at higher risk of developing CHD based on a TC:HDL-C ratio of at or above 4.5. However, it must be emphasized that there is a need to describe the shape of the curve of the TC/HDL-C levels and CHD risk before selecting a reference point to obtain a reliable estimate of the population at higher risk.

The use of TC:HDL-C to predict CHD may be an oversimplification. In only one study in the US, the Framingham Study, has the predictive power of the ratio been determined. Furthermore, it is unclear whether the ratio predicts CHD across all levels of TC.[16,17] □

Late Breaker Session on Injury Control Invites Abstracts

The Injury Control and Emergency Health Services special primary interest group of the American Public Health Association has announced it will again feature a "late breaker" session during the upcoming 119th APHA annual meeting in Atlanta. The session will be held on Tuesday, November 12, 8:30 AM–10:00 AM, and will feature work completed within the last few months—after the deadline for consideration in the regular symposia of the APHA annual meeting.

Abstracts of 250 words or fewer will be accepted by the Injury Control SPIG until September 10, 1991. Please send the abstract, title of the paper, author's name, address, and telephone number to: Richard Waxweiler, Division of Injury Control, Centers for Disease Control, Mail Stop F-36, Atlanta, GA 30333. Tel: 404/488-4695.

Physicians Promoting Bicycle Helmets for Children: A Randomized Trial

Robert Cushman, MD, FRCP, William James, MD, FRCP, and Helen Waclawik, BScN, RN

ABSTRACT

Head injury is the leading cause of death and serious morbidity in bicycle accidents. There is good evidence to recommend helmets, yet few children wear them. We evaluated helmet promotion in a randomized trial targeting children presenting to primary care settings for routine ambulatory care. The intervention consisted of physician counseling and take-home pamphlets. The study involved 339 families, 167 in the intervention group and 172 in the control group. In a follow-up telephone call, 2 to 3 weeks later, only 7.2% of the intervention group had purchased helmets, compared with 7.0% of the control group (χ^2 = 0.0056, P = .94). During the latter half of the study, bicycle safety received considerable media attention in Ottawa, and the provincial medical society sponsored a $5 discount campaign. Therefore both groups were subject to community "co-intervention." Nonetheless, we were surprised that physician counseling made no additional impact. Our results and the success of certain community programs suggest that physicians interested in helmet promotion would do better to participate in the design and implementation of multidisciplinary campaigns. (*Am J Public Health.* 1991;81:1044-1046)

Introduction

Head injuries account for 70% to 80% of deaths and serious morbidity in bicycle-related injuries.[1-7] Children and young adults are at greatest risk, accounting for more than 50% of deaths, and cycling is well recognized as a leading cause of head injury in childhood.[8-13] There is ample evidence to recommend the use of helmets, yet relatively few cyclists wear them.[14-22] Surveys in Arizona and Ontario found helmet use was less than 2% among elementary and secondary school children, compared with rates of 10% to 20% in the adult population.[10,22]

This study was designed to evaluate the effectiveness of promoting the use of bicycle helmets during a routine primary care visit.

Methods

Study Design

We targeted families with one or more cyclists ages 5 to 18, presenting to their pediatrician's or family doctor's office for a routine ambulatory visit. Physicians exercised discretion and excluded families presenting for emergency care or other special circumstances, where helmet promotion would have been inappropriate. All participants received an envelope containing a brief one-page survey and a consent form. Parents were asked to list the cyclists by age and to provide information about bicycles and helmet ownership and use. Randomly flagged envelopes indicated to the physician which families were to receive the intervention. The control group received only the usual care.

The Intervention

The intervention consisted of helmet promotion counseling and take-home pamphlets. During an individualized orientation session, physicians were provided with a small plasticized cue card outlining facts about bike accidents and head injuries (Table 1). Physicians were also encouraged to use the pamphlets as a focus for discussion and to express their personal concerns about the dangers of riding without protective headgear.

Outcome Measure

At 2 to 3 weeks' postintervention, a research assistant made a follow-up phone call to tabulate helmet purchases. Positive respondents were also questioned about cost, brand, and place of purchase. The answers allowed us to assess the validity of the "yes" responses. Because helmet owners often ride without headgear, additional questions addressed helmet use.[23,24]

Statistical Analysis

We estimated a helmet purchase rate of 5% to 10% in the control group, and for our efforts to be worthwhile, sought a rate 2 to 3 times higher in the intervention group. Based on our calculations, using a

Editor's Note: See related editorial on p. 972.

TABLE 1—Helmet Promotion Cue Card Contents

1. Last summer over 100 children with bike related injuries were admitted to the children's hospital.
2. Every year more than 600 children in the U.S.A. die from bike accidents.
3. Most serious injuries and deaths result from head injury.
4. Bike accidents are the leading cause of head injury in childhood.

Bike helmets can reduce the number and severity of head injuries. We consider helmets to be standard equipment and we are encouraging all our patients who cycle to purchase and use them.

one-tailed α of .05 and a β of .1 to .2, we determined that a sample size of 300 would provide adequate power. It would allow us to detect an absolute increase of 10% in the helmet purchase rate, from 5% to 15% at the low end of the scale and from 10% to 20% at the high end. The χ^2 was used to compare the number of helmets purchased in the two groups. Baseline characteristics were assessed using χ^2 or t tests where appropriate.

Results

There were 167 families in the intervention group and 172 in the control group. A total of 288 children were allotted to each group. Small differences between the groups were not statistically significant (Table 2).

At follow-up, only 12 (7.2%) of the 167 families in the intervention group had purchased helmets, compared with 12 (7.0%) of the 172 families in the control group. The 0.2% difference in favor of the intervention group was neither clinically nor statistically significant ($\chi^2 = 0.0056$, $P = .94$). Calculation of the 95% confidence interval on this difference gives a margin of error of ±5.5%, meaning that there is only a 2.5% chance that the intervention might have increased the purchase of helmets by 5.7% (0.2 ± 5.5) (Table 3).

Discussion

While the intervention proved disappointing, we were a little surprised by the control group results. During the latter half of the study (summer 1989) helmet promotion received considerable media attention in Ottawa. The Ontario Medical Association, in conjunction with a local department store, offered a $5 discount on helmets with coupons displayed on posters in waiting rooms. Therefore, community "co-intervention" may have influenced the study. We also considered possible "contamination," whereby clinicians inadvertently offered the intervention to the control group. Physicians were briefed about randomization and the two arms of the study. Only the flagged envelopes contained the pamphlets, serving as the cue for counseling, and when we addressed this issue upon completion of the study, participants did not feel contamination was a problem.

The more important question is why helmet promotion produced no additional effect in the intervention group. We considered three possible problems: low-quality intervention, high rates of helmet use, and price. The intervention was deliberately designed for busy office practice. Counseling sessions were brief, and the material provided a framework for physicians to deliver the message in their own style. Physicians were not "hand-picked" for interest in the subject, nor for counseling skills. However, they were volunteers who received a personalized formal orientation, as well as informal monitoring, from the research assistant.

Approximately 26% of families owned at least one helmet at study entry.

TABLE 3—Helmet Purchases by Family

Group	Purchased Helmet	Did Not Purchase Helmet
Intervention	12	155
Control	12	160

On a per capita basis this probably compares with our emergency room finding, 13% in children following a bike injury, and should not have limited the impact of the intervention.[24] Finally, Ottawa is a relatively affluent community with 33% of households reporting an income of more than $50 000 in 1985. Price was identified in our follow-up as a minor deterrent compared with lack of interest and peer pressure.[25]

In a similar study conducted in an emergency room following bike injuries, our helmet promotion efforts were also ineffective.[26] Our experience contains a message of caution, as well as a challenge. Helmet promotion is now encouraged by medical societies. While such interventions may have an impact over time, we suggest the medical community seek additional strategies.[27] There is evidence from Australia, Canada, and the United States that community programs involving the media, schools, and youth groups are effective.[9,28,29] Physicians can play an active role in teaching parents and children that bikes are not just another toy and that helmets can go a long way in reducing the risks of head injury. However, helmets for children are still fairly innovative, and the promotional challenges suggest physicians would be more effective by participating in the design and implementation of multidisciplinary community campaigns. ☐

TABLE 2—Subject Baseline Characteristics

Characteristic	Intervention (n = 167)	Control (n = 172)	Total (N = 339)
No. of children	288	288	576
Age			
Mean (years)	9.62	9.30	9.44
SD	3.43	3.14	3.29
Range	5–17	5–17	5–17
Families owning one or more helmets for cycling (%)	24.6	27.9	26.3

Acknowledgments

This project was made possible by an emergency health services research grant (No. 00988N) from the Ontario Ministry of Health. We would like to thank all participating physicians and Christine Jenkins of the Ottawa-Carleton Safety Council.

Preventing and Postponing Death: Trends in Tennessee Infant Mortality

Joyce M. Piper, DrPH

ABSTRACT

Infants born in Tennessee between 1984 and 1988 experienced reduced mortality compared with those born in the 5 years previous. For all birthweight singleton infants, the reduction from 10.2 to 8.4 deaths per 1000 live births represents an 18% decline in mortality. The most impressive gain made was for very low birthweight (<1500 g) infants in the neonatal period, where mortality was reduced 24%. However, for these infants there was nearly a sixfold increase in the postneonatal mortality associated with prematurity-related causes. ***(Am J Public Health.*** **1991;81:1046–1048)**

Introduction

Evidence from the National Center for Health Statistics indicates that the rate of decline in infant mortality slowed during the 1980s.[1] Much of the progress made in the previous decade appears to be due to improvements in birthweight-specific mortality associated with care available at tertiary perinatal care facilities.[2–9]

One consequence of the impressive gains made by these facilities in preventing the deaths of very low birthweight (<1500 g) infants has been the postponement of some deaths from the neonatal to the postneonatal period.[10–13] These postponed deaths are thought to have contributed to the lack of decline in postneonatal mortality during the 1970s. Little is known about this effect in more recent data.

To determine whether reductions in Tennessee infant mortality have been achieved during the 1980s and to quantify any evidence of a postponement effect, we reviewed vital records data for 1979 through 1988.

n	327 169	324 347	—	—

Note: NBW = normal birthweight; MLBW = moderately low birthweight; VLBW = very low birthweight.

Materials and Methods

Design, Population, and Data Sources

Two birth cohorts were studied: infants born in the period 1979 to 1983 and 1984 through 1988. Infants were grouped into two 5-year periods to dampen year-to-year rate fluctuations. Criteria for study entry included singleton live birth during 1979 through 1988, a birthweight of 500 to 5999 g, maternal race either White or Black, and Tennessee residence at birth and, for those infants who died, a death with recording of the vital events in Tennessee.

Infant death certificates were matched to corresponding birth certificates using a computerized linkage algorithm. Overall, birth information was available for 97.0% of the infants who died from the 1979 to 1983 birth cohort and for 96.7% of the infants who died from the later birth cohort. Investigation of a sample of the unlinked infant death certificates revealed that most were attributable to infant surname changes.

Study Definitions

Infants were classified into three birthweight categories: normal birthweight (NBW = ≥2500 g), moderately low birthweight (MLBW = 1500 to 2499 g), and very low birth weight (VLBW = <1500 g).

Analysis

The study analysis compared mortality rates for the two birth cohorts. Rate differences were calculated by subtracting rates of the 1979 to 1983 cohort from those of the 1984 to 1988 cohort. Confidence intervals (CI) of differences were calculated with standard techniques.[14]

We aggregated infant deaths into eight leading cause of death categories, as suggested by Dollfus et al.[15] This categorization scheme uses underlying cause, as reported on death certificates and coded with the International Classification of Disease, Ninth Revision (ICD-9), to group infant deaths that have similar etiologies or strategies for prevention.[15]

Results

In each of the three birthweight categories (NBW, MLBW, VLBW) there were reductions in the infant mortality rate for the later birth cohort, and these reductions were most pronounced for VLBW infants (Table 1). There were also reductions in neonatal mortality rates for all three groups, the greatest reduction occurring for the VLBW infants. However, reduction in postneonatal mortality was limited to NBW infants.

To examine these results further, we classified infant deaths for VLBW and MLBW infants using the categorization scheme previously described. For VLBW infants, there were reductions in the neonatal mortality rate for deaths associated with prematurity, birth asphyxia, and obstetric conditions (Table 2). However, for these infants, the postneonatal mortality rate for deaths associated with prematurity increased from 3.1 to 17.8 per 1000 live births. For MLBW infants, there were reductions in the neonatal mortality rate associated with prematurity (rate difference = −1.8, 95% CI of the difference −2.3–−1.3) and perinatal infections (rate difference = −2.1, 95% CI of the difference −3.3–−0.9). For these infants, there were no changes in the causes of postneonatal mortality.

Discussion

Our data show reduced infant mortality for infants born between 1984 and 1988 compared with those born in the five years previous. For infants of all birthweights the reduction from 10.2 to 8.4 deaths per 1000 live births represents an 18% decline in infant mortality. The most impressive gain made was for VLBW infants in the neonatal period, where the mortality rate declined from 332.4 to 251.9 deaths per 1000 live births, a 24% decrease. There was a small improvement in postneonatal mortality overall, but no improvement in this parameter for either MLBW or VLBW infants. For VLBW infants, there was nearly a sixfold increase in postneonatal mortality associated with prematurity-related deaths, suggesting that more of these fragile newborns are surviving the neonatal period only to die later of the complications of preterm birth.

It is unlikely that ascertainment bias could account for our findings, because we were able to link the same proportion of infant deaths to their birth certificates in the two time periods. The computerized scheme we used to group infant deaths of related causes was not subject to differential investigator surveillance. However, it is possible that changes in the attribution of underlying cause of death over time could have resulted in the increase of prematurity-related postneonatal deaths observed.

The postponement of the deaths of some VLBW infants from the neonatal to the postneonatal time period remains evident when data from the middle to late 1980s are compared with data from the early 1980s. These postponed deaths

TABLE 2—Neonatal and Postneonatal Mortality Rates by Cause of Death for Very Low Birthweight (VLBW) Infants Born in Tennessee, 1979 to 1988

[a] Sudden infant death syndrome.

probably represent an inevitable consequence of the application of technologically advanced medicine to multiple problems of high-risk newborns. Those concerned with improving infant health need to continue to examine both neonatal and postneonatal mortality, because early survival alone may not provide a complete picture. □

A Comparison of Breast-Feeding Data from the National Surveys of Family Growth and the Ross Laboratories Mothers Surveys

Alan S. Ryan, PhD, William F. Pratt, PhD, Jeffrey L. Wysong, MS, Gregory Lewandowski, MS, James W. McNally, MA, and Fritz W. Krieger, MS

ABSTRACT

This study compares rates of breast feeding reported in the National Surveys of Family Growth with those from the Ross Laboratories Mothers Surveys. Both surveys have documented rates of breast feeding over the last 30 or more years. Despite differences in survey methodology, both surveys document similar long-term trends in breast feeding. The similarities of rates in breast feeding also are evident across several maternal sociodemographic characteristics. We conclude that both surveys produce reliable and useful estimates of breast feeding. (*Am J Public Health.* 1991; 81:1049–1052)

Introduction

The principal sources of information on breast-feeding trends in the United States are the National Surveys of Family Growth (NSFG) and the Ross Laboratories Mothers Surveys (RLMS). These two surveys have documented trends in breast feeding over the last three decades. This study compares reported rates of breast feeding in the NSFG with those in the RLMS between 1955 and 1987 and compares the rates in 1987 according to selected sociodemographic characteristics.

We found that despite differences in survey methodologies and design, both surveys document similar trends in breast-feeding, and these similarities are evident across sociodemographic characteristics. The similarities of breast-feeding rates bear witness to the usefulness of the surveys in documenting the incidences and long-term trends of breast-feeding practices in the United States.

Methods

National Surveys of Family Growth

Information on breast-feeding has been collected by the National Center for Health Statistics in four NSFGs: Cycle I (1973), Cycle II (1976), Cycle III (1982), and Cycle IV (1988).[1–5] The surveys were designed to provide information on factors affecting childbearing, such as contraception, sterilization, infertility, and related aspects of maternal and infant health.[6] In addition to a series of detailed demographic questions, during a face-to-face personal interview, each mother was asked, "When your child was an infant, did you breast-feed (him/her) at all?" (i.e., ever-breast-fed).

Because the surveys focused on fertility, the NSFG included samples that were representative of the national population of civilian noninstitutionalized women in their reproductive years (ages 15 through 44 years). Cycles I and II had sample sizes of 9800 and 8600 women, respectively, who were currently or previously married. Cycle III included 7969 women of all marital statuses and women living in group quarters. The Cycle IV target population was expanded to include women living in Alaska and Hawaii. In Cycle IV, 8450 women were selected; this sample was drawn from households interviewed between October 1985 and March 1987 for another NCHS survey, the National Health Interview Survey (NHIS). The response rate to the NHIS was 96%, and the response rate to Cycle IV of the NSFG was 82% of the women subsampled from the NHIS. Thus, the total NSFG Cycle IV response rate is approximately 79%.

Ross Laboratories Mothers Surveys

Ongoing surveys by Ross Laboratories have documented trends in breast feeding in the United States since 1955.[7–12] The RLMS is a large, national mail survey designed to determine patterns of infant feeding during the first 6 months of life.

Each quarter, questionnaires are mailed to mothers when their infants reach 6 months of age. Mothers are asked to recall the type of milk fed to their infant immediately after birth, typically in the hospital, and during each month of the first 6 months of life.

The sample is derived from a list of births that consists of approximately 70% to 82% of all new mothers in the United States. The list includes names from hospital sources, county records of birth reg-

1987[a]	56.3	56.1	54.7

[a] RLMS breast-feeding data have been adjusted to reflect time that survey was mailed (adjusted year = last half of year + first half of following year; see text).

istrations, photography and entrepreneurial services, and newspapers.

Throughout the past few years, the number of questionnaires mailed to new mothers has increased substantially. In 1984, 56 894 questionnaires were mailed and 30 694 (54%), or 0.8% of annual births, were returned. In 1987, 154 958 questionnaires were mailed and 83 240 (54%), or 4.1% of annual births, were returned.

The collected infant-feeding data are then weighted by subclass means in the sample to account for differing responses and coverage rates. The subclasses were defined by the variables that have historically been associated with breast-feeding: maternal region of residence, ethnic background, age, and education. The weights were assigned using continually updated information from the US Bureau of the Census and National Center for Health Statistics.[13–16]

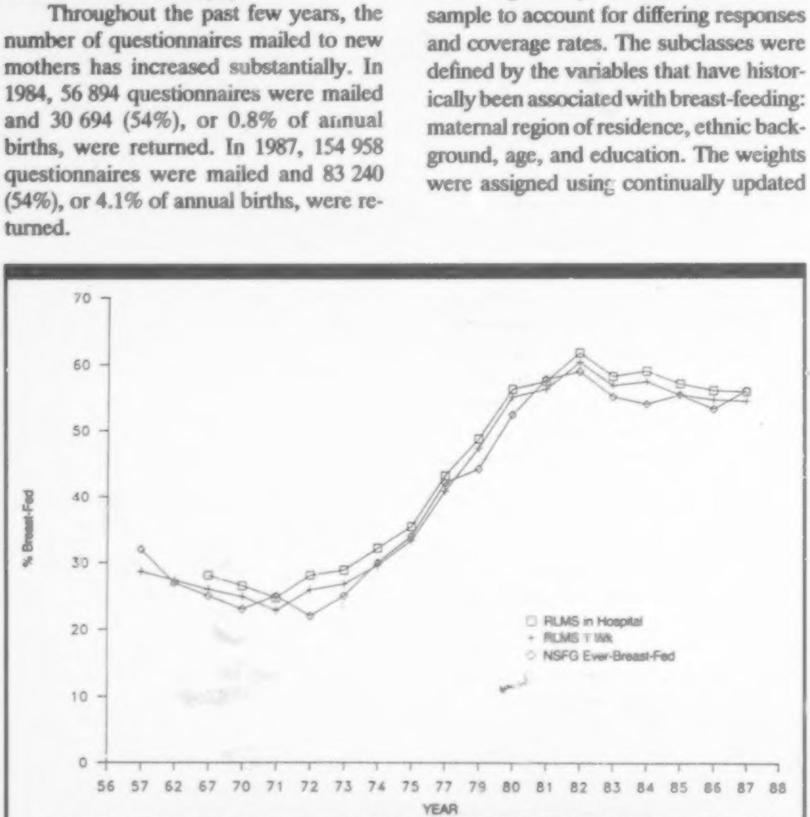

FIGURE 1—Incidence of breast feeding, 1957–1987: National Surveys of Family Growth (NSFG) compared with Ross Laboratories Mothers Survey (RLMS). The term "breast feeding" is defined as the exclusive use of human milk or the use of human milk with a supplemental bottle (i.e., formula or cow's milk).

Data Analyses

Breast-feeding rates reported at two time periods in the RLMS (in the hospital and at 1 week of age) were compared with the ever-breast-fed rates reported in the NSFG. We also considered rates of breast feeding in 1987 (most recent data in both surveys) according to the following sociodemographic characteristics: maternal age, parity, ethnic background, education, region of residence, and birthweight.

Because the RLMS questionnaire is mailed to mothers when their infants are 6 months of age, to produce yearly estimates that are comparable to those provided in the NSFG, it was necessary to adjust for the time the RLMS survey was mailed. For example, the adjusted data for 1987 represent information collected during the last half of 1987 and the first half of 1988 (Table 1). These adjusted data may differ slightly from previously published data that have not been adjusted.[11]

Since the data in the RLMS and NSFG were obtained through complex sample designs, it was necessary to use specific statistical techniques that incorporated the sample weights for the computation of estimated breast-feeding percentages and standard errors.[6,17,18] Differences between rates of breast-feeding in the two surveys were tested for statistical significance using a z test ($P<.05$).

Results: Trends in Breast Feeding

Both surveys show a small decline in the incidence of breast feeding from 1955 to the early 1970s, followed by an increase until 1982, when the incidence of breast feeding reached its peak (Figure 1). Between 1957 and 1988, the two surveys demonstrate an approximate twofold net increase in the incidence of breast feeding (32.0% to 56.3% in NSFG; 28.7% to 54.7% in RLMS at 1 week of age). Since 1982, as reported in RLMS, the incidence in the initiation of breast feeding and breast feeding at 1 week of age steadily declined (61.9% to 56.1% in the hospital; 60.5% to 54.7% at 1 week of age). The NSFG ever-breast-fed data showed a statistically nonsignificant net decline between 1982 and 1987 (59.1% to 56.3%).

Since 1955, at each year, differences between the two surveys in rates of breast-feeding were not large. Over time, the av-

[a] Breast feeding reported at 1 week of age.

[b] Infants who have been breast fed at any time.

[c] $P<.05$.

[d] The sample sizes for these demographic subsets do not add to total because of unit nonresponse.

erage difference between the NSFG ever-breast-fed and the RLMS in-hospital breast-feeding rates was 2.6%; differences ranged from 0.3% in 1971 to −6.1% in 1972. At each year, the RLMS in-hospital breast-feeding rates tended to be higher than the NSFG ever-breast-fed rates.

Differences between the NSFG ever-breast-fed and the RLMS breast feeding at 1 week of age rates were smaller than differences between the NSFG ever-breast-fed and RLMS in-hospital rates; the average difference was only 0.6%, and differences ranged from 3.3% in the period 1955 to 1959 to −3.9% in 1972 (Figure 1).

As shown in Table 1, both surveys demonstrated that in 1987, breast-feeding was relatively high among women who were White, older in age, college educated, living in the urban and western regions of the United States, and who had an infant of normal birthweight. Also, according to both surveys, the lowest rates of breast feeding were among women who were Black, with less than a college education, residing in the rural and southern regions of the country, younger in age, and who had an infant of low birthweight.

The *z*-test analyses indicated that across the socioeconomic subgroups considered, except for the northeast region, differences in breast-feeding rates between the two surveys were not statistically significant (Table 2).

Discussion

The present study indicates that over the last 30 or more years, differences in breast-feeding rates between the NSFG and RLMS surveys were small. Both surveys agree in showing a decline in breast-feeding from 1955 to the early 1970s, followed by an upward trend until 1982. They also agree in demonstrating that, across several selected maternal characteristics, certain subgroups of mothers are more likely to breast-feed than others.

The NSFG ever-breast-fed rates and the RLMS breast feeding at 1 week of age rates were comparable (Table 1). The RLMS in-hospital breast-feeding rates averaged approximately 2% to 3% higher than the NSFG ever-breast-fed rates. In the NSFG, mothers were asked if they ever breast-fed their infant, whereas in the RLMS, mothers were asked to indicate the kinds of milk they fed to their infant. A possible explanation for the lower in-hospital breast-feeding rates in the NSFG is that respondents who fed breast milk to their infant in the hospital but not after leaving may have considered such a brief encounter a nonexperience. In contrast, mothers in RLMS were not asked if they actually "breast-fed"; they may have given their infants a bottle containing expressed human milk. Because the questions used to define breast-feeding were not strictly comparable, the observed differences in the in-hospital breast-feeding rates may reflect variation in the manner in which mothers define breast-feeding.

Except for breast-feeding in the northeast region of the United States, across all other sociodemographic subgroups of mothers, differences in breast-feeding rates between the two surveys were not statistically significant. Considering the many comparisons that were made between these two surveys on mothers' characteristics, the finding of a single, statistically significant difference is not surprising and probably warrants little attention.

The principal sources of data on long-term trends in breast-feeding are the National Surveys of Family Growth and the Ross Laboratories Mothers Survey. The similarities in estimates support the usefulness of these surveys for documenting rates of breast-feeding in the United States. ☐

Risk Factors for Childhood Homicides in Ohio: A Birth Certificate–Based Case-Control Study

Kim A. Winpisinger, MS, Richard S. Hopkins, MD, MSPH,
Robert W. Indian, MS, and Jeptha R. Hostetler, PhD

ABSTRACT

Death certificates of children less than 8 years of age who were killed between 1979 and 1986 were linked to their Ohio birth certificates and compared with those of Ohio children born in 1983 (controls). Having an unmarried mother increased risk of homicide almost fivefold (odds ratio 4.87). Having a teenage mother, a mother who had not graduated from high-school, and being of Black race or low birthweight each increased the risk by approximately threefold. Increases in the proportion of children born to unmarried mothers may contribute to increases in childhood homicide rates. (*Am J Public Health.* 1991;81:1052–1054)

Introduction

Rates of death by homicide in children have increased markedly in the United States and in Ohio in the last 30 years, particularly for children under age 5.[1–3] While many of the risks associated with childhood homicide are known,[4–11] we undertook a case-control study of homicides in Ohio children under the age of 8, to identify risk factors and to clarify the associations among those factors.

Methods

Cases were taken from death certificates of child homicide cases (International Classification of Disease, revision 9 [ICD-9] codes E-960 through E-969) from the years 1979 through 1986, of Ohio residents who were born during those same years. For each case, the birth certificate was sought in the Ohio birth certificate file, matching on last name, first three letters of first name, and date of birth. Con-

TABLE 1—Characteristics of Ohio Child Homicide Cases, Ages 0 to 7 Years, 1979–1986, and 1983 Ohio Birth Cohort Controls

Characteristic	Case	Control
Born out of wedlock (%)	54.2	19.6
Black race (%)	38.0	15.1
Low birthweight (%)	16.2	6.7
Mother not a high school graduate (%)	47.4	20.8
Pregnancy complications (%)	12.0	9.6
Illness in pregnancy (%)	4.2	3.4
Singleton birth (%)	96.5	97.9
Male (%)	60.6	51.2
Mother's age (mean years)	21.9	25.3

TABLE 2—Odds Ratios (ORs) and Confidence Intervals (CI) for Selected Risk Factors for Child Homicide in Ohio Children, Ages 0 to 7 Years, 1979–1986, Compared with 1983 Ohio Births as Controls

Risk Factor	OR[a]	95% CI[b]
Born out of wedlock	4.87[a]	3.45–6.89
Black race	3.52[a]	2.47–5.02
Low birthweight	2.75[a]	1.71–4.38
Mother not a high-school graduate	3.45[a]	2.43–4.88
Pregnancy complications	1.32	0.77–2.24
Illness in pregnancy	1.29	0.51–3.02[b]
Singleton birth	0.57	0.22–1.57[b]
Labor complications	1.15	0.78–1.68
Metro county resident	1.52[a]	1.04–2.21
Congenital anomalies	0.55	0.03–3.64[b]
Teenaged mother	3.20[a]	2.23–4.60

[a] Statistically significant

[b] Less than five frequencies per cell

trols, also obtained from Ohio birth certificates, were all children born live to Ohio residents in 1983.

Factors examined in this study included marital status of the victim's mother at the time of the victim's birth, race (Black vs White), educational attainment of the mother (<12 years vs ≥12 years), county type (metropolitan vs nonmetropolitan), birthweight (<2500 g vs ≥2500 g), mother's age (teenager or ≥20), presence or absence of birth complications, illness during pregnancy, labor complications, multiple birth, and congenital anomalies.

Odds ratios (ORs) were calculated for each of these potential risk factors. Those risk factors associated with the outcome in a univariate analysis were examined in a stratified analysis, two at a time. Cornfield's method was used to calculate 95% confidence limits around the odds ratios.[12]

Results

There were 189 children who were born and died during the study period; birth certificates were identified for 140, or almost 75%. Of these, 134, or 96%, were under age 5. Mean age at death was 1.1 years. Children for whom birth certificates could not be found were more likely to be Black (48% vs 39% for whom certificates were found), metropolitan residents (78% vs 30%), and/or less than 28 days old at the time of death (29% vs 7%).

Cases were more likely to be Black, male, and of low birthweight than controls (Table 1). Likewise, case mothers were younger at the time of the child's birth and less likely to be married or to have a high school diploma.

Univariate ORs (Table 2) were highest for being born out of wedlock, Black race, having a mother who did not finish

TABLE 3—Crude and Stratified Odds Ratios (ORs) for Homicide, Ohio Cases under 7 Years of Age from 1979 to 1986, Compared with All 1983 Ohio Births

Risk Factor	Out-of-Wedlock Birth	Black	Teenaged Mother	Metro County Residence	High School Nongraduate	Low Birthweight

high school, having a teenaged mother, having a birthweight less than 2500 g, and living in a metropolitan county.

The effect of having an unmarried mother on risk of homicide was strong in all subgroups examined (Table 3), but was greatest among children whose mothers were age 20 or older, and/or lived in a metropolitan area, and among children who were of normal birthweight.

The crude risk of homicide associated with Black race was 3.52 (Table 3), but the risk fell to between 1.5 and 1.8 when separate strata of children born to married and unmarried mothers were examined. Thus, the apparent effect of Black race on risk of homicide is largely explained by the fact that a larger proportion of Black infants were born to unmarried mothers. The effect of Black race on risk of homicide is greatest in children residing in metro counties, in low-birthweight children, and in children with mothers over age 20, and varies little by educational status of the mother.

The crude risk of dying from homicide is increased approximately 3.2-fold when the child's mother is a teenager at the time of the child's birth. The magnitude of this increase in risk is greatest when the child is otherwise at lower risk.

The crude OR for metropolitan residence is only of modest magnitude (1.52), but the increase in risk is much greater when the mother is not a high school graduate or when the mother is Black.

Children born to mothers who did not finish high school (a proxy for low socioeconomic status[13–15]) are approximately 3.45 times more likely to become homicide victims than are children born to high school graduates. This OR estimate appears to be confounded in part by effects of race, mother's age, and marital status, as the stratum-specific estimates for both strata of all three variables were noticeably less than the crude OR.

Low birthweight was a significant risk factor for homicide in most subgroups. Low birthweight is more strongly associated with risk of homicide among Black than White infants, and among children whose mothers were married and age 20 or older at the time of their child's birth.

Discussion

Many of the expected relationships found in other studies were observed in these data: children of younger, poorly educated mothers, Black children, children of low birthweight, children whose mothers were unmarried at the time of the child's birth, and children who resided in metropolitan areas were all more likely to be killed than other children. In general, these variables appear to be independently associated with the risk of homicide. Variables associated with the pregnancy were not good predictors for risk of homicide, nor were congenital malformations. The effect of race is largely explained by the high prevalence of Black infants with unmarried mothers. Similarly, the crude effect of low educational attainment of the mother on risk of homicide appears to be explained in part by the fact that these mothers are more likely to be unmarried. A weaker effect of having an unmarried or teenaged mother on risk of homicide was seen when the infant was otherwise at lower risk. This suggests that other social supports in the child's environment may reduce the risk of homicide.

The consistent association of homicide risk with being born to an unmarried mother is striking in these data. It is unclear whether this finding represents a causal relationship, or whether both increased risk of homicide and being born to an unmarried mother are consequences of some other risk factor that was not captured in our study. If there is a causal relationship, we can expect the incidence of childhood homicide to continue to increase, because the percentage of Ohio children born to unmarried mothers has increased dramatically in recent years (Table 4).

Children have many health and social problems, which makes the causes of childhood homicide complex. However, interventions to help teenagers finish high school, begin careers, and find permanent life partners before becoming parents would probably help prevent childhood homicide and abuse.[16] Such interventions are, in any case, desirable for other reasons. The strong associations between having a young or unmarried mother and the risk of homicide suggest that interventions to prevent homicides in children should focus on these social variables. ☐

Costs and Benefits of Implementing Child Survival Services at a Private Mining Company in Peru

Karen G. Foreit, PhD, Delia Haustein, MD, Max Winterhalter, MD, and Ernesto La Mata, MD

ABSTRACT

Costs and savings of child health services were studied in a private mining company in Peru. Despite considerable outlays for medical services, few children under age 5 were vaccinated, and half of their illnesses went untreated. Children who were attended at the company clinic usually received unnecessary medication. As a result of the study, the company hired additional staff to provide integrated maternal-child preventive health care and family planning and contracted for intensive training and periodic on-site supervision. In less than 2 years, vaccination coverage reached 75%, and virtually all children under age 1 were enrolled in growth monitoring. Prescriptions were reduced by 24%, including a 67% drop in antimicrobials. The cost of the new services was $13 200 for the first 2 years. Approximately $6800 has been saved in pharmaceuticals prescribed for respiratory infection and diarrhea. Recently, two more mines adopted maternal and child health and family planning services. It is hoped that cost-benefit arguments will encourage other companies to incorporate aggressive child survival measures into their health plans. (*Am J Public Health.* 1991;81;1055–1057)

Introduction

As public resources stagnate, developing countries must find alternative sources of financing for primary health. One underutilized resource is the commercial sector. Approximately 10% of the 1984 health expenditures in Peru were covered by payments made by employers,[1] a source that could be tapped for preventive health care.

Most commercial health plans only cover curative care. The present study examined whether expenditures for curative child health care could be reduced through preventive interventions and better prescription practices, while maintaining or improving quality of care. The study site was a privately owned Peruvian mine that provides medical coverage to approximately 800 workers and 4000 dependents, including 900 children under age 5.

Despite company investments of $1.7 million in welfare and medical care, the population showed high morbidity. A prospective cost-benefit analysis found that family planning and child survival services could improve health status, at a cost that would be compensated by savings in other services averted. The company implemented the recommended services; this report summarizes the findings of the child survival component.

Methods

Baseline conditions were assessed during 1986 and 1987. Data included company records and household and clinic surveys. The household survey was conducted in July 1986, with a random sample of 220 miners' wives. The clinic survey was conducted in March 1987 and included 132 consultations with children under age 5. Preventive health services were added in 1988. A follow-up conducted in late 1989 included service statistics, a campwide census, and a clinical survey that captured 206 visits by children under age 5. Wholesale costs of medications prescribed were calculated at baseline and at follow-up.

Results

Baseline Conditions

Infant and child health were precarious at the start of this study. Infant mortality was estimated at 120 deaths per 1000 live births. Contributing factors included lack of well-baby care, low vaccination coverage, high incidence of diarrhea and respiratory infection, and overmedication and use of inappropriate medications.

Lack of well-baby care. All consultations surveyed were motivated by illness. Physicians reported that they had no time for well-baby care and that mothers would not use it if it were offered.

Vaccination. The household survey found that fewer than 5% of the children ages 1 to 4 were completely vaccinated. No child was vaccinated during an observed clinic visit. A quarter of the children over age 1 who had not been vaccinated spontaneously reported having had measles.

Morbidity. Of the children surveyed, 44% reported diarrhea and/or cough in the last 3 days; 24% reported diarrhea and 29% cough. Half the reported cases of diarrhea and/or cough did not seek treatment. Nevertheless, children under age 5, although they make up only 17% of the population, accounted for 50% of all clinic visits. Etiology was not determined, but the high incidence of blood and/or mucus in the stool accompanied by vomiting suggests shigellosis.[2] Respiratory infection accompanied by diarrhea is characteristic of rotovirus.

Overmedication. International norms suggest minimal medication for di-

No. of cases	47	85	24	44	28	14	21	21

[a]ARI = acute respiratory infection.

TABLE 2—Projected and Actual Costs and Estimated Cost Savings of Child Survival Activities

		Actual Costs		Estimated Savings	
Item	Projected Costs	Year 1	Year 2	Year 1	Year 2
Training and supervision	1500	1657	1946		
Salary and benefits	6300	2807	6666		
Equipment and materials	265	154	0		
Total	8065	4618	8612	1618	5147

arrhea and respiratory infection: oral rehydration and ampicillin for diarrhea with blood or mucus, acetaminophen and benzathine penicillin for moderate respiratory infection, etc. Nevertheless, every patient under age 5 received at least 2 and on average 3.7 medications, regardless of symptoms. Prescriptions for respiratory infection and diarrhea exceeded international recommendations (see Table 1). Prescriptions were classified according to the *Physician's Desk Reference*[3] and its Peruvian counterpart, *Diccionario de Especialidades Farmaceuticas*.[4]

Intervention

The study recommended that the mine hire an additional physician and nurse to provide well-baby and maternal care, and follow World Health Organization norms[5] for treating acute respiratory infection (ARI) and diarrhea. First-year costs were estimated at $8065; projected savings in pharmaceuticals ranged from $10 600 to $12 600 per year.

The company hired extra staff and contracted for training and on-site supervision. Services began in May 1988, in coordination with a national vaccination campaign. During the first quarter of 1989, standardized diagnostic and treatment protocols for ARI and diarrhea were adopted, and management contracted for a second year of supervision.

Program Impact

Vaccination coverage. The census found 75% coverage among children ages 1 to 4. Virtually all children under age 1 had been appropriately vaccinated.

Well-baby care. Of all clinic visits made in November 1989, 16% were for well-baby care, compared with none at baseline. Approximately 90% of children under age 1 and 35% of children ages 1 to 4 had been enrolled in growth monitoring. Thirty-nine children with second- and third-degree malnutrition were enrolled in nutritional rehabilitation; 31% returned to normal.

Treatment of diarrhea and respiratory infection. During 1989 the clinic treated 2258 cases of respiratory infecion and 1233 cases of diarrhea among children under age 5. As shown in Table 1, physicians prescribed on average one fewer medication per consultation; mean number of antimicrobials prescribed for ARI and diarrhea decreased from 1.5 to 05.

Costs and Savings

During the first 2 years, the company invested $13 200 in new child services at a cost per capita of less than $7.50 per year, compared with baseline per capita expenditures of $160 for curative care. After 18 months, annual prescription savings were approximately $5000 (January 1990 prices). Assuming linear trends, savings during the first 2 years totaled $6800 without considering improved health status due to better vaccination and nutrition practices. Table 2 presents program costs and estimated savings.

Discussion

Most child survival efforts focus on children outside the formal health system. However, many children inside the system also do not have access to preventive care. Furthermore, access to curative services does not guarantee use of services or that appropriate treatment will be given if sought. Consequently, even children covered by private plans may suffer from poor health, and company costs are inflated by improper prescription practices.

The present study demonstrates that preventive health can be provided at modest costs and achieve significant savings. Mothers accepted well-baby services and had no complaints about reduced medications. The advantages to the employer of preventive health care are clear. In 1989, two more mines initiated services. If the model is replicated throughout the mining community, more than 200 000 children in the most remote locations in Peru will benefit. ☐

Measles Vaccination Coverage among Latino Children Aged 12 to 59 Months in Los Angeles County: A Household Survey

Donnell P. Ewert, MPH, J. Conley Thomas, PhD, MPH, Lorraine Y. Chun, MPH, Robert C. Enguidanos, MPH, Stephen H. Waterman, MD, MPH

ABSTRACT

A high rate of measles transmission has occurred in Los Angeles County since 1987. To determine measles vaccination coverage among Latino preschoolers, the group at highest risk of measles during this period, a cluster survey was conducted among Latino households with children aged 12 to 59 months. Of 279 children enrolled, 240 (86%, 95% confidence interval = 81% to 91%) reportedly had received the measles vaccine. Measles vaccination coverage among Latino preschoolers in Los Angeles County is insufficient to halt measles transmission within this subpopulation. (*Am J Public Health.* 1991;81:1057–1059)

Introduction

The incidence of measles in Los Angeles County (LAC) was less than 2.0 cases per 100 000 person-years from 1985 to 1987, but measles incidence increased to 7.3 in 1988[1] and 15.3 in 1989[2] (Table 1), with Latinos experiencing the highest rate among all ethnic groups during both years. Of the 1366 probable and confirmed measles cases occurring between January 1988 and June 1989, 601 (44%) were Latino preschoolers, the group at highest risk during this period.[2]

To promote early immunization and to reduce the number of children susceptible to measles, the LAC Department of Health Services lowered the recommended age of measles-mumps-rubella (MMR) vaccination from 15 to 12 months of age in July 1988.[3] During 1989, the same agency conducted a household cluster survey among Latino preschoolers to assess vaccination coverage.

Methods

The household survey was performed with a cluster sampling technique similar to that commonly used by the World Health Organization's Expanded Programme on Immunization (EPI).[4,5] The sampling frame included the 344 census tracts in LAC consisting of 50% or more Latino residents; two thirds of LAC Latinos reside within these census tracts. Census tracts were determined to be 50% or more Latino based on the 1980 census, adjusted for reported births and deaths through 1988.

Thirty census tracts were systematically selected from the sampling frame with probability proportionate to size. After random number tables and coin flips were used to select a street and initial household within each census tract, households were visited consecutively until seven eligible households were included in the survey. Households were not revisited if no one responded to a knock on the door.

Household inclusion criteria were permanent residence of a child aged 12 to 59 months who had at least one Latino parent, and presence of a respondent at least 16 years of age who was willing to participate. Latino was self-defined by the respondents and was generally understood to mean of Latin American descent. Possession of a written vaccination record

was not required but was used if available. All eligible children in the household were included in the survey.

A standard interview form was used to obtain family information and vaccination history of the child(ren). A child was considered vaccinated against measles if the child had received either MMR or monovalent measles vaccine from any source on or after the first birthday. Interviewers were bilingual (English/Spanish) and conducted interviews between 9 AM and 5 PM on weekdays, from July 18 through September 13, 1989.

Age of vaccination was calculated from the birth and vaccination dates of children with written vaccination records. Confidence intervals (CIs) for the vaccination coverage point estimates were calculated using the method described by Lemeshow and Stroh.[6] Statistical significance was assessed with Mantel-Haensel χ^2 statistics, but these CIs may be too narrow because the survey did not employ a simple random sample.

Results

Of the 1684 households visited during the survey, an adult was present at 909 (54%), 676 of which were Latino. Of the 273 Latino households with eligible children, 209 (77%) agreed to participate. Fifty-one (80%) of the 64 refusals to participate were from secondary caretakers, who denied knowledge of vaccination history. The survey included 279 children, and the child's mother was the respondent for 221 (79%).

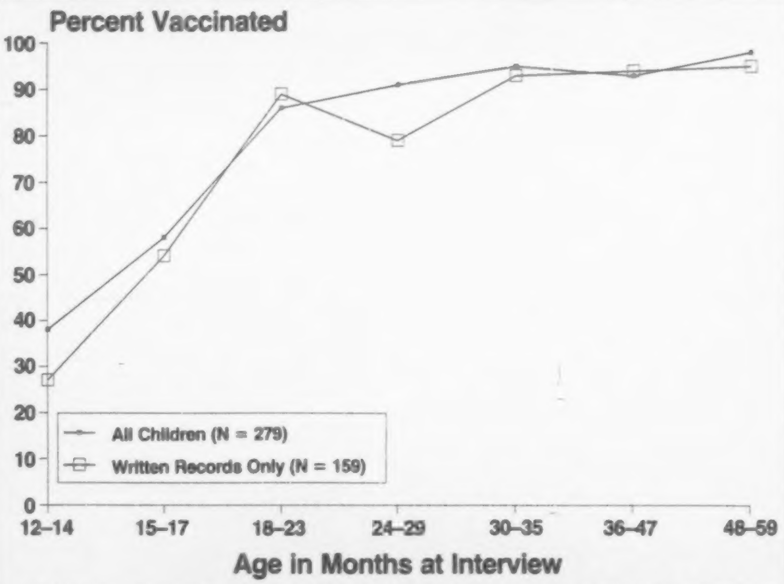

FIGURE 1—Proportion of Latino Children Residing in Predominantly Latino Census Tracts in Los Angeles County Who Were Vaccinated Against Measles, by Age Group, 1989

Respondents reported that 240 (86%; 95% CI = 81%–91%) of the children had received measles vaccine. Of the 201 children aged 24 to 59 months, 190 (95%) reportedly were vaccinated, compared with 50 (64%) of the 78 children aged 12 to 23 months (odds ratio [OR] = 9.7; 95% CI = 4.5–20.7) (Figure 1).

Written vaccine records were available for 159 (57%) of the children. Measles vaccine had been received by 131 (82%; 95% CI = 75% to 90%) of these children, a smaller proportion than that reported for children without written records (90%; 95% CI = 86–96%) (Figure 1). Mean age of measles vaccination was 19.5 months for the 131 vaccinated children, and mean age at interview was 21.5 months for the 28 unvaccinated children. Of the 46 children aged 15 to 29 months, 22 (48%) were vaccinated before 16 months of age, compared with 33 (34%) of the 98 children aged 30 to 59 months (OR = 1.8; 95% CI = 0.9–3.7) (Figure 2). Of the 112 children who were at least 2 years of age, 76 (68%) had been vaccinated before their second birthday.

Discussion

Effective measles vaccination programs aim to vaccinate a large enough proportion of susceptible persons (typically 92% to 96%) to attain herd immunity.[7] However, in nonrandomly mixed populations, such as the population of LAC, the number of susceptible persons and the frequency of their contact are more important in limiting transmission than the proportion of immune individuals within the whole population.[8] Because measles transmission was primarily focused in preschool children during 1989 and measles vaccination coverage was less than 92% to 96% among Latino preschoolers, endemic transmission will likely continue among Latinos in LAC until the number of susceptible preschool children decreases substantially, either through natural infection or vaccination.

Measles vaccination was delayed on the average until about 20 months of age among Latino children in this survey, and more than two thirds of the nonvaccinated children were younger than 24 months of age. These findings highlight the importance of delayed vaccination in the estab-

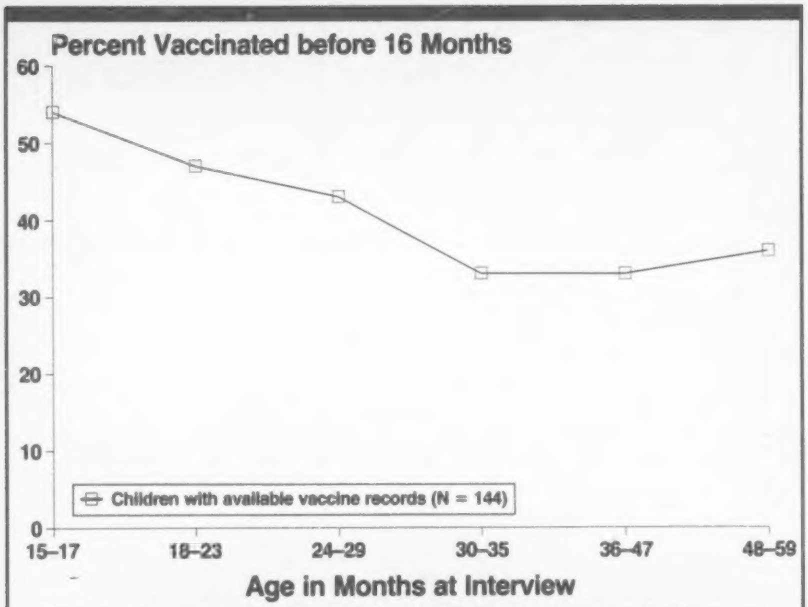

FIGURE 2—Proportion of Latino Children Residing in Predominantly Latino Census Tracts in Los Angeles County and for Whom Vaccine Records Were Available, Who Were Vaccinated Against Measles Before 16 Months of Age, by Age Group, 1989

lishment of a pool of children susceptible to measles. Fortunately, since the July 1988 change of recommended age of MMR vaccination from 15 to 12 months, the proportion of children vaccinated before 16 months of age has steadily increased (Figure 2).

The higher coverage reported among children without written records may reflect a tendency for the caretakers of these children to report vaccination for unvaccinated children. Inclusion of these children may have resulted in an overestimation of vaccination coverage. Also, children with mothers working outside the household may have been undersampled, since households were not revisited if no one answered the door or a knowledgeable respondent was not present. The effect of this potential bias on the coverage estimate is unknown.

Our sample variation from EPI—selection of seven households instead of seven children per cluster—had a negligible effect on the coverage estimate. An analysis that excluded the children who would not have been included in an EPI sample revealed a less than 1% difference in vaccination coverage. However, nonprobability sampling at the second stage, an inherent problem of the EPI-style survey, may have had some unknown effect on the vaccination coverage estimate.

Measles continues to affect primarily preschoolers in LAC, and the new two-dose MMR vaccination schedules recommended by the American Academy of Pediatrics[9] and the Immunization Practices Advisory Committee[10] will not reduce measles incidence among these children. Since about 95% of children receiving a second dose of MMR are already immune to measles,[11] public health efforts should focus on protection of unvaccinated preschoolers in areas where these children constitute the main risk group and resources are limited. ☐

Low-Level Air Pollution and Upper Respiratory Infections in Children

Jouni J. K. Jaakkola, MD, Mikko Paunio, MD, Martti Virtanen, MD, and Olli P. Heinonen, MD, DSc

ABSTRACT

Effects of low-level air pollution were studied in one polluted city and two reference cities in northern Finland by comparing the frequency of upper respiratory infections over a 12-month period in 1982 as reported by parents of children ages 14 through 18 months (n = 679) and 6 years (n = 759). A similar comparison was carried out between children living in the more polluted and less polluted areas of the polluted city. The annual mean and the greatest half-hour concentrations of sulfur dioxide (23 and 807 $\mu g/m^3$), particulates (31 and 291 $\mu g/m^3$), nitrogen oxides (15 and 160 $\mu g/m^3$), and hydrogen sulfide (2 and 177 $\mu g/m^3$) in the polluted city were mainly due to industrial sources. In the reference cities, air pollution was produced mainly by traffic and heating. Adjusted odds ratios (OR) for one or more upper respiratory infections of residents in the polluted city vs those in the reference cities were 2.0 (95% confidence interval [CI] = 1.3–3.2) in the younger age group and 1.6 (95% CI = 1.1–2.1) in the older age group. Within the polluted city, OR calculated for living in more vs less polluted areas were 2.0 (95% CI = 1.0–4.0) in the younger and 1.6 (95% CI = 1.0–2.7) in the older children. The present results suggests that, for children, air pollution can be hazardous in concentrations lower than those recorded in earlier studies from Britain and central Europe. The synergistic effect of sulfur dioxide, particulates, nitrogen oxides, hydrogen sulfide, and other pollutants may be a contributing factor. (*Am J Public Health.* 1991;81:1060–1063)

Introduction

Several studies in the 1960s showed that children living in areas with sulfur dioxide (SO_2) and particulate levels above 100 $\mu g/m^3$ had an increased occurrence of respiratory symptoms, upper and lower respiratory tract illnesses, and lower levels of pulmonary function than children living in less polluted areas.[1–5] The evidence is controversial on the effects of air pollution at levels lower than 100 $\mu g/m^3$.[6–9] However, a recent study from Israel reported a significantly higher prevalence of respiratory symptoms and conditions in second- and fifth-grade children living in an area of Israel with an annual average of only 30 $\mu g/m^3$ SO_2 than in children of a less polluted area.[9]

We evaluated the effect of low-level air pollution by comparing the frequency of upper respiratory infections in infants and preschool children in Oulu (polluted city), the northernmost industrial city in Finland, and in two cities with little industrial ambient air pollution, Vaasa (southern reference city) and Rovaniemi (northern reference city); see Figure 1.

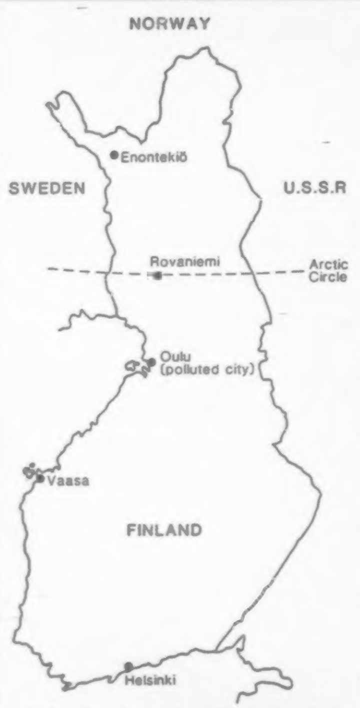

FIGURE 1—Location of Oulu, the Polluted City, and Vaasa and Rovaniemi, the Reference Cities.

Methods

Oulu (population 96 000) is located on the Baltic coast. Vaasa (coastal, population 54 000) and Rovaniemi (inland, population 31 000) are the closest southern and northern cities with an approximately similar level of urbanization but with little industrial air pollution in the downtown areas.

Four main pollution sources encircle the town center of Oulu (Figure 2). A sulfite cellulose pulp mill including a power station, northwest of the center, is the biggest source of sulfur dioxide (SO_2) pollution (2500 tonnes/y). The main source of nitrogen oxides (NO_x), a chemical plant producing acids and fertilizers, lies to the northeast. To the southwest a sulfate cellulose pulp mill, which is a source of hydrogen sulfide (H_2S) and methyl mercaptan (CH_3SH), causes odor disturbance. The heating plant of Oulu University Hospital, in the southeast, is an important source of SO_2 and particulates.

All cities monitor SO_2 and particulate concentrations. In the polluted city, H_2S and NO_x concentrations have also been measured since 1983. The measured concentrations from 1982 to 1984 are summarized in Table 1.

This paper was submitted to the journal February 6, 1990, and accepted with revisions April 2, 1991.

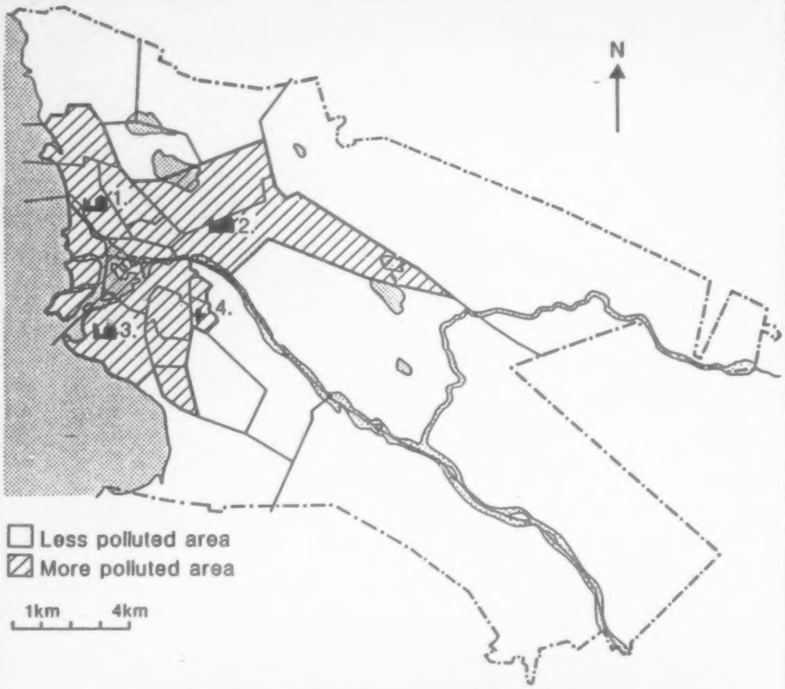

FIGURE 2—The Polluted City Divided Into Areas of More and Less Pollution: Building 1, Sulfite Cellulose Pulp Mill and a Power Plant; Building 2, Chemical Plant; Building 3, Sulfate Cellulose Pulp Mill; and Building 4, University Hospital.

Although the long-term mean levels of SO_2 were only slightly greater in the polluted city than in the reference cities, there were more frequent periods of short-term, high-level exposure to SO_2 due to downtown industrial sources. The population of the polluted city was exposed to considerably greater levels of H_2S, CH_3SH, and other malodorous sulfur compounds and nitrogen oxides.

The polluted city was divided into areas of more and less pollution according to the dispersal models of SO_2 made by the Finnish Meteorologic Institute. The more polluted area included all postal districts with an annual mean concentration of SO_2 ≥ 15 $\mu g/m^3$ and two postal districts with NO_x produced by the chemical plant but with SO_2 concentrations <15 $\mu g/m^3$. The less polluted area included those districts with an annual mean SO_2 concentration <15 $\mu g/m^3$ together with low levels of NO_x (Figure 2).

[a] Concentrations in reference cities estimated to be low due to lack of sources.

The data on health status were collected during the first two months of a mumps-measles-rubella vaccination program in November and December 1982. The total number of children ages 14 to 18 months was 679 (364, 190, and 125 from Oulu, Vaasa, and Rovaniemi, respectively) and the total of children age 6 years was 759 (310, 305, and 144, respectively).

During the vaccination visit, a nurse checked individual health records and interviewed the parents as to name, age, sex, the number of upper respiratory infections with fever (common cold, otitis media) during the previous 12 months, allergic diseases confirmed by physician (obstructive bronchitis or asthma, allergic rhinitis or conjunctivitis, and atopic dermatitis), passive smoking at home, and the number of daily contacts with other children at home and day care. The socioeconomic status of parents was obtained from the 1980 national census but was available only for older children.

The adjusted odds ratios for upper respiratory infections for those living in the more polluted vs the less polluted area were estimated in logistic regression analyses (see Appendix). The outcome was dichotomized (no infection = 0, one or more infections = 1). Similarly, other independent variables in the model were dichotomized. A child having any of the allergic diseases was considered atopic (no = 0, yes = 1). The main effects model was fitted by taking the determinant of interest (exposure) and all the other potential determinants of upper respiratory infections in the model. Meaningful interaction terms were considered according to their statistical significance ($\beta/SE[\beta] < 1.96$).

Results

In the polluted city, both younger and older children had had more upper respiratory infections during the previous 12 months than children in the reference cities (Table 2). Within the polluted city the children in the more polluted area had had more infections than children in the less polluted area. The distributions of potential confounders in the polluted and reference cities are presented in Table 3.

TABLE 2—The Occurrence of Upper Respiratory Infections in the Polluted vs Reference Cities

No. of infections during previous 12 months	Polluted city			Southern reference city n (%)	Northern reference city n (%)	Total n (%)	Unadjusted Odds Ratio[a] (95% confidence interval[b])
	More polluted area n (%)	Less polluted area n (%)	Total n (%)				
			14- to 18-month old children

[a] All polluted vs reference.
[b] Miettinen's test-based method.

The only difference of note was the number of daily child contacts for 6-year-old children.

Living in the polluted city vs reference cities was a significant risk factor for upper respiratory infections in both age groups when adjusting for potential confounders in logistic regression analysis (Table 4, Appendix). The adjusted odds ratio (OR) was 2.0 (95% CI [confidence interval] = 1.3–3.2) in the younger age group and 1.6 (95% CI = 1.1–2.1) in the older age group. Living in the more vs less polluted area of the polluted city was also a significant risk factor for upper respiratory infections in younger children (Table 3). The adjusted OR was 2.0 (95% CI = 1.0–4.0), i.e., a 100% increase in the frequency of children with infections. In 6-year-old children the corresponding adjusted OR was 1.6 (95% CI = 1.0-2.7), which was nonsignificant ($P < .10$), but the number of children in this analysis was small. When the less polluted area was enlarged to include surrounding municipalities, the adjusted OR became significant, 2.0 (95% CI = 1.3–3.0). There were no significant interactions in the comparisons between the more and less polluted areas.

TABLE 3—The Occurrence of Risk Factors in the Study Populations of Polluted and Reference Cities

Passive smoking at home						
Yes	52 (39.1)	68 (38.4)	120 (38.7)	102 (33.4)	62 (43.1)	164 (36.5)
No	81 (60.9)	109 (61.6)	190 (61.3)	203 (60.6)	82 (56.9)	285 (63.5)
Atopic disease						
Yes	37 (20.9)	29 (21.8)	66 (21.3)	48 (15.7)	31 (21.5)	79 (17.6)
No	140 (79.1)	104 (78.2)	244 (78.7)	257 (84.3)	113 (78.5)	370 (82.4)

multivariate analysis. There was no municipal gas distribution in any of the cities studied. Passive smoking, daily child contacts, and atopic disease were included in the logistic models. Socioeconomic classification obtained from the 1980 census was available for the older age group. The differences in socioeconomic distribution between the cities were found to be small.

The data collection was blind: neither the participants nor the interviewers were aware of the purpose of the study. Thus the potential information bias caused by knowledge of children's exposure status was eliminated.

In conclusion, our results suggest that children's respiratory health can be jeopardized from exposure to air pollution in concentrations much lower than those recorded in earlier studies from Britain and central Europe. The synergistic effect of SO_2, particulates, NO_x, H_2S, and other pollutants may be a contributing factor. ☐

TABLE 4—Crude (cOR) and Adjusted Odds Ratios (aOR) for Having Experienced an Upper Respiratory Infection during the Past 12 Months in Polluted vs Reference Cities and in the More vs Less Polluted Area of the Polluted City

Population	cOR	aOR	95% CI[a]
14- to 18-month-old children			
Reference cities	1.0	1.0	
Polluted city	2.1	2.0	1.3—3.2
Less polluted area	1.0	1.0	
More polluted area	1.9	2.0	1.0—4.0
6-year-old children			
Reference cities	1.0	1.0	
Polluted city	1.5	1.6	1.1—2.1
Less polluted area	1.0	1.0	
More polluted area	1.5	1.6	1.0—2.7

Adjustment was made by logistic regression analysis controlling for sex, daily child contacts, atopic disease, and passive smoking.

[a] CI = confidence interval.

Discussion

The ambient air in the index city was more polluted than in the reference cities due to the industrial sources around the town center. There were also differences in air pollution across the polluted city. However, the differences in the annual mean concentrations of SO_2 between the cities and within the polluted city were small. Moreover, in terms of international comparison, the levels in the most polluted area in the polluted city (25 $\mu g/m^3$) can still be considered low-level air pollution. However, the industrial sources in the polluted city cause higher and more frequent peaks of SO_2 than are caused by heating and traffic in the reference cities. Industrial NO_x, H_2S, and CH_3SH emissions were the main qualitative differences in comparing the polluted city with the reference cities.

We found a significant association between the occurrence of upper respiratory infections and living in an air-polluted area. This finding was consistent in both 14 to 18 month olds and 6 year olds (and combined) when comparing the polluted city with the reference cities and when comparing the more and less polluted areas within the polluted city. Most of the potential confounders were controlled for either by the study design and/or in the

APPENDIX—Regression Coefficients Produced by PROBIT Procedure of SPSSX

Risk factor	Polluted vs reference city: Younger children β (SE)	Polluted vs reference city: Older children β (SE)	Polluted vs reference area[a]: Younger children β (SE)	Polluted vs reference area[a]: Older children β (SE)
Living in polluted city or area	0.357 (0.110)	0.221 (0.082)	0.339 (0.174)	0.256 (0.139)
More than 4 daily child contacts	0.423 (0.306)	0.121 (0.099)	0.476 (0.522)	−0.289 (0.161)
Atopic disease	0.224 (0.187)	0.140 (0.105)	0.152 (0.254)	0.073 (0.163)
Passive smoking	0.114 (0.124)	−0.140 (0.081)	−0.058 (0.185)	−0.084 (0.133)
Male sex	−0.131 (0.108)	0.025 (0.079)	−0.115 (0.170)	0.109 (0.131)
Intercept	5.674	5.217	5.926	5.596

Note: All the variables are coded yes = 1 and no = 0.

The final equation for polluted vs reference city, younger children is:

logit [pr(INFECTION = 1 /POLLUTED, CONTACTS, ATOPIC, PASSIVE, SEX)] = Intercept + 0.357(POLLUTED) + 0.423(CONTACTS) + 0.224 (ATOPIC) + 0.114(PASSIVE) − 0.131(SEX)

The procedure calculates the estimates from LOGIT model:

$$\{LOG[p/(1-p)]\}/2 + 5 = \text{Intercept} + \beta X$$

This means that aOR can be calculated:

$$aOR = e^{2\beta}$$

and the 95% confidence limit is

$$e^{2\beta \pm [illegible]}$$

Decline in the Use of Illicit Drugs by High School Students in New York State: A Comparison with National Data

Denise B. Kandel, PhD, and Mark Davies, MPH

ABSTRACT

A school-based epidemiological survey of the use of drugs was carried out in Spring 1988 among 7,611 adolescents representative of students in grades 7 through 12 in New York State public and private schools. This survey provides the most recent data on the use of crack in that population. Comparison with a statewide survey carried out five years earlier reveals a large decline in the use of illicit drugs in that period. This decline appears to be stronger than the decline reported for national samples. (*Am J Public Health.* 1991;81:1064–1067)

Introduction

National epidemiological surveys[1,2] document a decrease in the use of illicit drugs starting in 1980 for marijuana and in the mid-1980s for cocaine. We report results from a 1988 survey of high school students in New York State (NYS) which reveals large declines in the use of illicit drugs over five years. The decline appears to be stronger in the Northeast than in the United States as a whole and sharper in NYS than in the entire Northeast.

Methods

A statewide epidemiological survey of the use of alcoholic beverages, cigarettes, marijuana, cocaine, crack, and other illicit drugs was conducted among 7,611 students in grades 7 through 12 in NYS in Spring 1988.

The two-stage random sample represents junior and senior high school students attending NYS public and private schools. A stratified sample of 54 schools and two homerooms from each grade per school was selected. The four stratification criteria for school selection were: 1) geographical area; 2) proportion White enrollment; 3) public versus private; 4) size of enrollment. Active or passive parental consent for the child's participation was obtained, as required by individual schools. A school in New York City was dropped because only 10 percent of parental consent forms were returned. Students answered anonymous self-administered structured questionnaires in classrooms (84 percent completion rate). The sample was weighted to reflect the variable probabilities of selection of schools and homerooms and the grade-specific absentee rate in each school; 95 percent confidence intervals were calculated using empirical standard errors from 10 random subsamples drawn from the total sample. For grade-specific rates, the standard error was estimated by multiplying the standard error, assuming simple random sampling, by the average design effect (1.53).

Results

Prevalence of Student Drug Use

The rates of use follow patterns reported by others,[4,5] but probably underestimate drug use among adolescents in the population, since school absentees and dropouts were not included (Table 1).[6–9]

Trends Over Time

In 1983, the NYS Division of Substance Abuse Services (DSAS) surveyed a representative sample of students in grades 7 to 12 from 206 public and private schools selected from a stratified sample of health service areas.[3] Structured self-administered questionnaires were given in classrooms. (Completion rates are not provided.).

Comparison of rates in 1983 and 1988 reveals sizable declines of at least 50 percent over five years in the use of almost every illicit drug, but no change in alcohol use (Table 1).

Comparison with National Data

The declines in NYS schools are striking and parallel those reported nationally for high school seniors in the Monitoring the Future (MF) study by Johnston, *et al.*[1] and for adolescents ages 12 to 17 in the population reported in the National Household Survey (NHS)[2] (Table 2). [Lower rates are reported in the household (NHS) than the school (NYS) survey,[10] and may reflect in part differences in mode of survey administration.] This decline may be greater in NYS and the Northeast than nationally. Over two years, the prevalence of cocaine use reported by high school seniors declined by 43 percent in the Northeast (23 percent in

1986 versus 13 percent in 1988[1,11]), compared to 28 percent nationally (17 percent versus 12 percent). We compared the changes in rates in NYS over comparable periods in MF (1983–1988) and NHS (1982–88) (Table 3). For NYS, we calculated odds ratios for 11th–12th graders, since separate 1983 data for the 12th grade were not available.

The odds ratios are consistently and significantly higher in NYS than in the nation, except for sedatives and tranquilizers. In MF, the ratios are slightly higher in the Northeast than in the total sample and significantly different for marijuana, cocaine and stimulants.

Discussion and Conclusion

The decline in drug use appears to be sharper in areas where rates were initially the highest. This differential decline may be explained by changes in the age structure of the US population, peer influence processes, and the relative commitment of youth to substance use in areas with high compared to low use prevalence. Substance use is most prevalent in the late teens and early twenties.[2,5] The downward trend in illicit drug use prevalence from 1980 to 1988 parallels the decline in the ratio of youths (aged 15–24) to the parental generation (aged 34–44) between

the early and late 1980s, from 1.7 to 1.1. (The upward trend in prevalence from 1960 to 1980 paralled the upward trend in the ratio of youths to adults.) Fewer members in one's age cohort and smaller relative cohort size will reduce opportunities for social interactions with one's peers, a most important factor in drug use initiation,[14] and increase social control by the older generation.[15,16] Perceived risks and disapproval associated with illicit drug use have increased.[17,18] Although changes in relative cohort sizes are almost identical in NYS and the US, the sharper decline in drug use prevalence in NYS could be accounted for by the structural factor, if changes in individual behavior depend not only on opportunities for peer interactions but on group norms and drug users' characteristics. The rate of decline in drug use may follow a reverse diffusion process characteristic of epidemics, and may accelerate as a function of the number of individuals initially exposed, especially if proscriptive norms also become more negative and individuals at risk for drug involvement are less deviant. In areas with high prevalence of drug use, less deviant youths will be drawn into drug use, mainly through peer influence. The high use areas would show more rapid decline in prevalence than areas with low prevalence, where the pool of existing and potential users would include individuals more committed to drugs.

The decrease in lifetime drug use observed among NYS students cannot be attributed to an increase in school dropout rates by drug-using adolescents, thereby leaving in schools an increasing number of non-drug users, since the dropout rate has been declining.[15]

These epidemiological data contrast with data on treated or clinical cases, which have shown dramatic increases throughout the 1980s,[20] although recent data on cocaine-related emergency room admissions show declines.[21] There may be a time-lag between initiating drug use and experiencing drug-related problems; smoked cocaine now accounts for a large part of clinical cases.

The most extreme forms of drug use may be concentrated in disorganized communities that are not well represented in school or household samples. Whether the situation in these communities has deteriorated over the last decade is not known. We may be moving toward an increasingly polarized society, in which drug involvement is another dimension, besides lower economic and social resources and higher social pathologies,[22] on which groups are divided and the gap between them is becoming greater.[22,23] There would be youths in school and mainstream society, who have decreased their drug use, and those in urban ghettos and out of school, who have increased their use.[24] Strengthening the educational system and youth's investment in their schooling and future may be a most promising way of reducing involvement in such activities as drug use, which are destructive for self and society. ☐

Surveillance of Attempted Suicide among Adolescents in Oregon, 1988

Jon K. Andrus, MD, David W. Fleming, MD, Michael A. Heumann, MPH, James T. Wassell, PhD, David D. Hopkins, MS, and Jane Gordon, PhD

ABSTRACT

In January 1988, Oregon became the first state to require hospital-based reporting of attempted suicide (AS) in all adolescents < 18 years old. From January to December 1988, 644 cases of AS were reported (annual rate of 214 per 100 000 population, ages 10 to 17 years). We compared these 644 cases of AS with all 137 Oregon adolescents < 18 years old who committed suicide in Oregon during the 10-year period 1979 through 1988, and found that the strongest predictor of outcome was method used. (*Am J Public Health.* 1991;81:1067–1069)

Introduction

Nationally, suicide is the third leading cause of death among adolescents and young adults.[1] For each completed suicide, 30 to 200 suicides are attempted, but not completed.[2–6] Ten percent of adolescents who attempt suicide make further attempts within 1 year, and 31% do so within 2 years.[7,8]

In Oregon, suicide among teenagers is second only to motor vehicle injuries as a cause of death, accounting for 16% of deaths in Oregonians ages 13 to 19.[9,10] In 1987 the Oregon legislature mandated the reporting of all attempted suicides among persons younger than 18 years. This paper summarizes the first year (1988) of information from this surveillance system and compares the characteristics of adolescents who attempted suicide in 1988 with those who completed suicide in Oregon during the 10-year period 1979 to 1988.

Methods

Beginning January 1988, each Oregon hospital (n = 70) was required to report to the Oregon Health Division information on all adolescents younger than 18 years who attempted suicide. An attempted suicide was defined as self-inflicted injury or condition specified by the medical provider as having fatal intent, treated at a hospital or a hospital emergency department.

Information collected by the hospital included demographics, date and place of attempt, family living situation, history of previous suicide attempts, use of alcohol, results of blood alcohol testing if done, and method of attempt. This information, without name identifiers, was sent monthly to the Health Division.

For comparison, state death certificates and medical examiner's reports were used to identify all Oregon adoles-

cents 10 to 17 years old who committed suicide in Oregon during the years 1979 to 1988. A completed suicide was defined as a person who died as a result of intentional self-inflicted injuries as determined by the medical examiner.

In this study, the term adolescent means 10- to 17-year-olds. Adolescents who attempted suicide but were not successful are termed attempters, adolescents who committed suicide are termed completers, and incidence rates are expressed per 100 000 population of 10- to 17-year-olds. Rural counties were those with less than 15 000 population; suburban were those with populations of 15 000 to 35 000; and urban were those with greater than 35 000 population.

Population data were obtained from the Bureau of the Census and the Center for Population Research and Census at Portland State University. For attempters, we used 1988 mid-year population estimates for denominators to calculate annual incidence rates. For completers, we used 1984 population estimates. Annual incidence rates were calculated for completers using 10 years of data from 1979 to 1988. This methodology was chosen after we had compared the characteristics of completers from 1979 to 1983 with those from 1984 to 1988 and found no differences by age, sex, race, or method of attempt.

Data were analyzed using Dbase, EPIINFO, and SAS. Exact confidence limits were calculated using methods based on Fisher's Exact Test.

Results

In 1988, 644 Oregon adolescents ages 10 to 17 years were reported to have attempted suicide, an annual incidence rate of 214 per 100 000. There were no attempted suicides in children younger than 10 years. Of attempters, 87.7% were aged 14 to 17 years, 83.5% were female, 84.9% were White, and 19.8% were urban residents (Table 1).

Only 9.5% (61/644) of the attempters had blood alcohol tested. Of those tested, 50.8% had detectable blood alcohol levels. The medical examiner tested 41.6% (57/137) of the completers for blood alcohol. Of completers tested, 35.1% had documented detectable blood alcohol at the time of their death.

From 1979 to 1988, 137 Oregon adolescents committed suicide, an average annual incidence rate of 4.6 per 100 000. The ratio of the average annual incidence rates of attempters to completers was 47:1. The average annual incidence rates for both attempted and completed suicide was lowest for 10 to 11 year olds and highest for 16 to 17 year olds (Table 2).

Compared with attempters, completers were more than 20 times more likely to be male and 2 times more likely to be White (Table 1). There were no statistically significant differences between attempters and completers by residence, place of attempt, day of the week, or season when the self-inflicted injury occurred.

Attempters more frequently used drug overdose as a method, while completers more frequently used firearms (Table 3). Gunshot wounds and hanging were strong predictors of fatal outcome. These two methods were used by 89.1% (122/137) of the completers compared with 2.2% (14/644) of the attempters (odds ratio [OR] = 366.0, 95% confidence interval [CI] = 162.8–844.8).

We performed a logistic regression analysis including the method, sex, race, season, residence, day of the week, and age. Choice of method was the strongest predictor of outcome ($P < .0001$). Although sex had the only other statistically significant predictor coefficient ($P = .002$), it had little effect on the predicted probability of outcome.

The univariate association of sex with outcome was primarily due to an association of sex with method. Combining data from attempters and completers showed that lethal methods were more likely to be chosen by males: 90.9% (30/33) of the hangings and 79.6% (82/103) of the shootings. In contrast, among those using stabbing or lacerations, 20.9% (14/67) were male; and among the drug overdosers, 13.0% (64/492) were male.

Discussion

In 1988, one adolescent suicide attempt with injuries severe enough to require emergency care was reported for every 467 Oregon adolescents. The ratio of attempted to completed suicide rates for those adolescents was 47:1. The overwhelming predictor of outcome was method used. Generally, adolescents who shot themselves died, while those who overdosed on drugs or lacerated themselves lived.

Collection of accurate prevalence or incidence data for attempted suicide has been hampered by a lack of central registries.[6,11] Results of limited surveys of high school students vary and have estimated that 5% to 15% of adolescents attempt suicide.[12–15] Our study showed that adolescent suicide attempts are common in Oregon and that statewide surveillance is feasible.

In this study, method and outcome were found to be inextricably linked. Thus the factors influencing one must also influence the other. Whether desired outcome determines method or the method available at the time of attempt determines outcome urgently needs clarification. For some adolescents who attempt suicide, selection of method may be paramount, and outcome will depend on method. For others, desired outcome may be decided first and selection of method will depend on that decision. Successful intervention is critically dependent on which of these two dynamics is operating. Securing firearms in a locked cabinet may not be helpful if a despondent adolescent will merely search for another lethal weapon. However, this intervention would be quite effective if the result were that an alternate, less lethal method would be used. Additional study is needed to determine factors influencing choice of method and to identify situations in which selection of method is not solely dependent on desired outcome, but is also influenced by other factors such as availability and social acceptability. □

Acknowledgments

The authors would like to thank Rocke Klockner, Joyce Grant-Worley, and Brent Marsden of the Oregon Health Division for their support during this study.

Nurses Claim Victory in Supreme Court Decision

"Registered nurses across the country have won a major victory in the United States Supreme Court," Dr. Barbara Redman, Executive Director of the American Nurses Association (ANA), recently announced.

The court upheld an ANA-backed position allowing for separate collective bargaining units in hospitals for registered nurses.

"This decision gives nurses the right to decide their destiny in the workplace," said Redman. "Nurses in many states across the nation have told us they are ready now to organize, and the ANA has allocated half a million dollars to state nurses associations to train organizers and help increase their organizing efforts."

"The ANA is uniquely positioned to handle an increased demand by nurses for assistance in determining workplace issues. We are the only national organization offering collective bargaining that is run by nurses for nurses," added Redman.

Redman said the ruling will lead to a stronger voice for nurses in promoting higher quality care for patients, adding value to the health care dollar.

Knowledge of Diagnosis and Reproductive History among Survivors of Childhood Plumbism

Howard Hu, MD, ScD, MPH

ABSTRACT

As part of a study of the long-term consequences of childhood plumbism, 35 survivors of lead poisoning in the period 1930 through 1944 were interviewed along with 22 controls matched for age, sex, and town of residence. Subjects were asked to recall all pregnancies they engendered (men) or carried (women), outcome, and intellectual development of resulting children. Matched female plumbism subjects reported a higher proportion of spontaneous abortion or stillbirths among pregnancies (relative risk = 1.60, 95% confidence interval [CI] = 0.6–4.0) and a higher proportion of learning disabilities among school-age children (relative risk = 3.0, 95% CI = 0.9–10.2) in comparison with their controls. There was no evidence of clustering of learning disabilities within families or confounding by parental educational level. These results suggest that women with a history of childhood lead poisoning may be at risk for having spontaneous abortions or stillbirths and having children who manifest significant learning disabilities. (*Am J Public Health.* 1991;81:1070–1072)

Introduction

Lead accumulated from past exposures is not inert, as previously thought; rather, it is probably released continually from storage sites.[1,2] More than 95% of stored lead in an adult is located in the skeleton. Recent mammalian animal studies have suggested that a significant fraction of skeletal lead content is mobilized, enters the circulation, and crosses the placenta during both pregnancy and lactation.[3,4]

Since lead is a well-known behavioral teratogen, even at relatively low levels of exposure, and skeletal lead stores are known to persist for decades, the possibility exists that lead can be a delayed transgenerational toxin, i.e., it can affect the next generation even after maternal exposures have long ceased.

We report results of a reproductive questionnaire administered to subjects participating in an investigation of the long-term consequences of childhood plumbism (lead poisoning). We also report the level of awareness that survivors of childhood plumbism had with regard to personal histories of lead exposure. All research described herein was approved by the institutional review boards of the Brigham and Women's Hospital, Boston Children's Hospital and Medical Center, and the Harvard School of Public Health.

Methods

Methods used to define, trace, and recruit eligible subjects are described in detail elsewhere.[5] In summary, we used microfilmed medical records to identify 192 subjects admitted to Boston Children's Hospital during the period 1930 to 1944 who met the following criteria for lead poisoning: (1) a definite history of pica for lead-containing material (usually paint) or the use of lead nipple shields, (2) evidence of dense metaphyseal bands ("lead lines") on at least one long bone x-ray, (3) clinical evidence of symptoms and signs characteristic of childhood lead intoxication, and (4) the absence of clinical evidence for rickets. Subjects with continued residence in Massachusetts were traced using available public records.

The current status of 145 (76%) subjects was ascertained. Of these, 102 were found with current Massachusetts addresses. The 72 who lived in the Boston area were sent letters recruiting them for a "study on the impact of the environment on health."

Thirty-five subjects participated in the study. In general, participants had a history of less severe plumbism than nonparticipants.[5] Also enlisted were 22 control subjects matched for age, sex, and neighborhood. Town books were used to identify eligible controls, and letters of recruitment were sent. Budget constraints prevented recruitment of matched control subjects for 13 of the childhood plumbism subjects.

Each participant received a package containing a self-administered questionnaire and instructions. The questionnaire included detailed medical, occupational, and environmental history components. Each subject was asked to list all known pregnancies (or engendered pregnancies, in the case of males) with dates; whether the pregnancy resulted in a miscarriage, still birth, live birth, or was voluntarily aborted; and the sex of live births. For each offspring that survived to school age, the subject was asked whether he or she had had a learning disability. This was defined as difficulty in school that either (1) resulted in being left back one or more grades or (2) required special in-school remedial education. Learning disability de-

fined similarly has been found to be associated with elevated dentine levels in a longitudinal study of teenagers.[6]

Results

Matched plumbism subjects did not differ appreciably from either the matched controls or the nonmatched plumbism subjects with respect to age, sex ratio, years of education, smoking status, alcohol ingestion, and medication use (Table 1).

In response to questions on childhood illnesses, 13 (37%) of all plumbism subjects noted being unaware of having had lead poisoning as children.

Among all plumbism subjects, women had 19 miscarriages or stillbirths out of a total of 79 pregnancy outcomes (24%), and 13 children with learning disabilities out of 60 school-age children (22%) (Table 2). Matched female plumbism subjects had 11 miscarriages or stillbirths out of a total of 51 pregnancies (22%), and 10 children with learning disabilities among a total of 40 school-age children (25%). Matched control subjects had 6 miscarriages or stillbirths out of 48 pregnancy outcomes (13%), and 3 learning-disabled children out of 42 school-age children (7%). The relative risk of matched female plumbism subjects for having a miscarriage or stillbirth was 1.60 (95% confidence interval [CI] = 0.6–4.0) and for having a learning disabled child, 3.0 (95% CI = 0.9–10.2). Inclusion of unmatched plumbism subjects did not appreciably alter these estimates. The pregnancies engendered by both the matched plumbism and control male subjects had few adverse reproductive outcomes. There were too few matched pair outcomes to offer meaningful analysis using McNemar's test.

TABLE 1—Participant Demographics and Severity Scores

Characteristic	Matched Plumbism Subjects	Matched Control Subjects	Unmatched Plumbism Subjects
n	22	22	13
Age			
Range (years)	49–60	48–60	47–60
Mean (years) ± SD	54.7 ± 4.0	55.4 ± 4.0	56.7 ± 4.0
Ratio of males to females	8/14	8/14	5/8
Education			
Range (years)	8–20	8–18	11–16
Mean (years) ± SD	13.5 ± 2.8	14.3 ± 2.9	12.9 ± 1.9
Smoking			
Never smokers	8	7	5
Former smokers	11	12	5
Current smokers	3	3	3
Usual alcohol ingestion			
<2 Alcoholic drinks per day	19	20	12
≥2 Alcoholic drinks per day	3	2	1

Discussion

The developing fetus and infant is clearly susceptible to the neurobehavioral effects of lead exposure. Efforts are currently under way to decrease such susceptibility by decreasing maternal exposures that have been associated with elevated lead levels in the blood, such as the use of leaded gasoline,[7,8] smoking and alcohol use,[9] and occupational exposures.[10]

Although this inquiry is of a small scale and produced results of borderline significance defined statistically, it provides evidence that remote exposures such as childhood plumbism may cause subsequent risk to a fetus or infant and result in later impairment of school performance. The relative risks found in this study may be underestimates, since study participants had been less severely intoxicated than nonparticipants.

This research also suggests that a significant fraction of individuals who had been diagnosed with lead toxicity as children are unaware of this history.

The presence of significant bias in this study seems unlikely. Other than a childhood history of plumbism, matched subjects did not differ from controls in terms of age, years of education, medication use, smoking, or alcohol ingestion. Studies that have examined the consistency of reproductive history questionnaires have generally not found significant recall bias.[11] Our analysis did not account for familial aggregation of adverse outcomes.[12] However, no more than two learning disabilities were observed in any one family in this study.

These results justify additional research efforts in this area. Overexposure to lead is still a widespread phenomenon among our society's children.[13] If lead poisoning poses a risk not only to these children, but also to these children's children, it may be important to screen young women entering reproductive age for lead burden and develop a strategy for prevent-

TABLE 2—Summary of Reponses to Reproductive Questionnaire

Editor Search Committee Seeks New Editor for American Journal of Public Health

An Editor Search Committee is actively seeking a replacement for Dr. Michel Ibrahim, who has announced his resignation as Editor of this Journal, effective January 1, 1992. The six-member search committee welcomes and solicits nominations and recommendations from the APHA membership and leadership to assist them in identifying the best available individual for this important salaried position. Nominations and statements of interest should be submitted by August 20, 1991; the committee will meet several times to consider suggestions, applications, and support materials of potential candidates.

Names of potential candidates, along with letters of endorsement and other support materials, should be sent to: Editor Search Committee, American Public Health Association, 1015 15th St., NW, Washington, DC 20005.

The following criteria will be considered by the search committee in selecting the Journal editor:

- Comprehensive knowledge and broad perspective of the field of public health, with an appreciative understanding of its many disciplines and solid grounding in the basic sciences of epidemiology and statistics;
- Professional accomplishment and identity with the public health field, including respected standing among peers, combined with an extensive network of professional contacts who can provide expertise in soliciting and evaluating materials for publication;
- Demonstrated research skills, with evidence (such as credited publication in peer reviewed journals) of firm grounding in a field of scientific inquiry within public health;
- Demonstrated writing, reviewing, and editing skills, enabling authoritative advice to authors on the suitability of prepared manuscripts, facilitating informed consideration of reviewer assessments, and equipping for the preparation of appropriate editorials as needed;
- Freedom to devote half time to editor duties;
- Working knowledge of APHA and sympathy to its advocacy goals;
- Easy access to Washington, DC;
- An institutional base is deemed highly desirable, preferably in a school of public health, a university health sciences center, or a large epidemiologic research/service organization.

APHA is an affirmative action/equal opportunity employer.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

spect to the AIDS epidemic: (1) Could an immediately available, nonpunitive maintenance program attract into treatment a significant number of presently unmotivated addicts and reduce their risk behavior? (2) If a large number responded, could clinics of this kind expand fast enough to meet demand, while keeping a balance with other programs providing full service? The authors approached these questions by restricting the study group to addicts on the waiting list of an established full-service program, with the understanding that they would be released from the study when an opening became available in the conventional program.

Even with this reduction in scope, the study was vigorously opposed by the treatment community and by the New York State Division of Substance Abuse Services—a result that provided an unequivocally negative answer to the question of feasibility. Although in principle it might be argued that addicts are a heterogenous mixture of persons with widely different social needs and therefore that a range of different programs (including special facilities for pharmacological induction and social evaluation during the first month of treatment) are needed for the efficient use of resources, the treatment community and governmental administration have spoken with a virtually unanimous voice: Minimum-service programs will be prohibited, even as preliminaries to full-service programs.

On May 23, 1991, the US Public Health Service working group on methadone treatment rescinded plans for a regulatory change that would have permitted the operation of interim facilities for addicts on waiting lists of licensed clinics. The goal for the future, apparently, is to eliminate the embarassment of waiting lists by discouraging narcotic addicts from applying for treatment. ☐

In: Glebatis DM, Novick LF, Stacy A. VIII. Hospitalization of HIV-seropositive newborns with AIDS-related disease within the first year of life. *Am J Public Health.* May 1991;81(suppl):46–49.

Four lines were omitted at the bottom of column 2 on page 46. The complete paragraph should read: "A total of 995 HIV-seropositive newborns born in December 1987 through June 1988 were confirmed in the Newborn HIV Seroprevalence Study. A total of 151 infants born during this time period were hospitalized with an ARD within 12 months of birth. Assuming that all members of the hospitalized set were members of the seroprevalence set, 15 percent of HIV-seropositive infants born in these seven months were hospitalized with an ARD within 12 months of birth. The monthly ratios ranged from 14 to 18 percent (Table 1)."

Adult Foster Care for the Elderly in Oregon: A Mainstream Alternative to Nursing Homes?

Rosalie A. Kane, DSW, Robert L. Kane, MD, Laurel Hixon Illston, MSPH, John A. Nyman, PhD, Michael D. Finch, PhD

ABSTRACT

Background. In Oregon, adult foster care (AFC) homes, which are private residences where a live-in manager cares for one to five disabled residents, have been covered by Medicaid since 1981 and seem to offer a mainstream alternative to nursing homes. They house almost 6000 older people, two thirds of which pay privately.

Methods. In a cross-sectional study, we interviewed 400 AFC and 400 nursing home residents. Data analyses included descriptive cross-tabulations; hierarchical loglinear models for judging the effects of care setting and payment status on resident characteristics; and logit analyses for predicting care setting and payment status within care settings.

Results. On average, nursing home residents were more physically and cognitively impaired than AFC residents, but there was considerable overlap in patterns of frailty in the two settings. Medicaid AFC residents were less disabled than privately paying AFC residents. AFC residents reported more social activity, even when we controlled for disability status. AFC residents and their families were more likely to value privacy and homelike settings when choosing a care setting, whereas nursing home residents were more likely to value rehabilitation and organized activity programs.

Conclusions. Both AFC and nursing homes are viable components of a long-term care repertoire. The greater disability levels of private-pay AFC residents refutes the criticisms that disabled Medicaid residents were being inappropriately channeled to AFC. (*Am J Public Health.* 1990;81:1113–1120)

Introduction

The repertoire of suggested care to supplant or supplement nursing homes has been growing, although demonstration research thus far has not shown the cost-effectiveness of such care in major randomized trials.[1–3] Lackluster results of demonstration projects are attributed, in part, to poor targeting of the new community care programs to people unlikely to enter nursing homes or to stay there for long. It is also inherently difficult to deliver home care as efficiently as nursing home care to people with heavy care needs. Economies of scale are required, and this, in turn, requires residential proximity of those needing care, which is certainly a characteristic of nursing homes.

This line of reasoning has led to enhanced interest in developing residential settings for functionally impaired persons that permit economies of scale in their care but allow the older disabled persons to preserve personal autonomy and privacy and have more control over their routines. In such living settings, the resident is not viewed first and foremost as a patient.

Study Setting

Adult foster homes, as they have developed in Oregon, provide one such residential setting. An adult foster home in Oregon is a private residence in a residentially zoned area that is licensed to care for one to five disabled adults. Each foster home must have a live-in resident manager (who may also own the home). Meals are served family style, and regulations are kept to a minimum to enhance a homelike atmosphere and autonomy for the residents. The resident manager provides personal care and housekeeping services. If necessary, other services, such as skilled nursing, can be brought into the foster home from home health agencies.

Although the idea of adult foster care is inherently attractive as a concept, several demonstrations projects in other states have failed to develop a strong market for the service.[4–8] However, Oregon's experience with adult foster care has been different in two ways. First, although Medicaid clients were the first to widely use adult foster care, by 1988 private-paying customers constituted more than two thirds of the nearly 6000 residents in foster care. Second, and related, in other states where foster care exists, the programs tend to be proportionately much smaller and largely serve low-income clients with mental illness or developmental disabilities.[9] Only in Oregon does adult foster care seem a mainstream possibility for the elderly.

The growth of adult foster homes in Oregon was stimulated in 1982 when the state made adult foster care a benefit under its Medicaid waiver program. To receive subsidies under this program, the adult foster care resident needed to be eligible for nursing home care on the basis of functional disabilities. The state developed a vigorous program to divert Med-

This paper was submitted to the journal December 10, 1990, and accepted with revisions May 1, 1991.

icaid clients already in nursing homes to foster homes when the routes to home had been cut off and urged clients who could no longer remain at home to consider adult foster care as an alternative to nursing home care. By 1988, adult foster care was widely accepted by the public as a desirable means of caring for older persons in need of a supportive environment.

Several facts about adult foster care in Oregon were clear. First, the growing utilization suggested that many elderly and families found adult foster care a desirable option. Second, the success of adult foster care within both the private and Medicaid markets (along with vigorous home care programs) was sufficient to reduce the demand for nursing home beds. Between 1981 and 1989, the supply of nursing home beds per 1000 persons aged 75 years and older fell from 50 to 40, and the occupancy rate decreased from 92% to 87%.[10] Oregon is the only state where nursing home use dropped in absolute as well as proportional terms. Third, adult foster care is a less expensive program than nursing home care; both the Medicaid rates and the average private pay rates in foster care were about 2/3 of those in nursing homes. And fourth, adult foster homes became the focal point for criticism from the nursing home industry, which claimed that the care was inadequate, that the degree of social stimulation was insufficient, and that the Medicaid program, in particular, was denying recipients access to the appropriate level of care.

In this context, the state of Oregon commissioned the University of Minnesota to evaluate the adult foster care program. The study had several components, including a mailed census of the foster care industry and a retrospective study of change over time using program data for the Medicaid population. Both of these will be reported in future papers. This paper reports the results of a cross-sectional comparison of 400 foster care residents and 400 nursing home residents. Our analysis looked at differences between care settings and differences between Medicaid and private pay clients within care settings. The ramifications of these questions for public policy extend beyond Oregon at a time when serious consideration is being given to tightening the regulation of group homes and some authorities argue that elderly people should be channeled to particular care settings on the basis of measurable functional characteristics.

Method

Sample

Between December 1988 and February 1989, we conducted in-person, structured interviews with 402 intermediate care facility (ICF) residents and 405 foster home residents in four geographic areas, the latter chosen to represent different facets of long-term care delivery in Oregon (i.e., rural vs urban, Medicaid administration by area agencies on aging vs by regional state offices of the Senior Services Division) while reflecting the average, typical state experience on descriptors such as proportion of elderly, and adult foster home and ICF bed-to-population ratios. Original data collection was necessary because, although considerable data are available about Medicaid residents living in adult foster homes and in nursing homes through their periodic assessments by case managers, little existing data are available on the private pay group in either setting, particularly in foster homes. Moreover, even the Medicaid data set has no information on social activities or choice of care setting.

We generated the foster care sample by randomly selecting foster homes in each geographic area and enrolling all residents of the selected foster homes until we reached the desired proportional number of respondents for each of the four regions. Enough nursing homes were selected randomly in each geographic area to allow us to interview 10 residents in each facility and achieve a number of subjects equal to the foster home sample. From a list of all ICF residents in the randomly selected homes, we randomly selected 5 Medicaid and 5 private pay ICF residents, thus reflecting the proportion of Medicaid and private pay residents in the population. (The nursing home sample was limited to ICF residents because the skilled nursing care level in Oregon is a very small program and widely agreed to include only very disabled and medically unstable persons who are not appropriately compared to adult foster home residents).

To reach the desired sample size of at least 400 residents in each care setting, 108 foster homes were included in the sample; only 4 foster homes approached refused to participate. The final nursing home sample included 39 facilities; only 2 nursing homes approached refused to participate. Participation of the sampled residents was also very high. Actual refusals to participate represented only 4%—6 ICF residents and 5 family members on behalf of a cognitively impaired ICF resident declined to participate. No refusals occurred among foster care residents.

Data Collection

Interviewers were recruited from the local areas and trained by University of Minnesota staff. Most had previous experience in human services or health care. Background information such as date of admission, payment status, medical diagnosis, and family member most knowledgeable about the resident (should a family proxy be needed) was first gathered from the care setting staff on each sample member. For this purpose, records were consulted when necessary. If the resident in either care setting seemed to be an unreliable informant, the interviewers were instructed to skip to a later section of the schedule and attempt to administer the mental status questionnaire. When few of the 10 MSQ questions were answered correctly, or when the resident was clearly too confused to answer, the interviewers moved to proxy respondents. Questions about choice of care setting and satisfaction with care setting were administered by telephone to a family member. The foster care home's resident manager or a nursing home staff member who knew the resident best served as the proxy respondent for questions about current physical functioning, activities, and recent use of hospitals, emergency rooms, and physicians.

Instruments

Identical questions were asked of adult foster home and ICF residents (merely interchanging the terms "adult foster home" and "nursing home" when appropriate.) The functional abilities of the residents were measured through questions carefully designed to be compatible with those found in the SSD 360 (the comprehensive assessment format used by case managers to provide a database on all Medicaid waiver clients in Oregon.) Activities of daily living and instrumental activities of daily living (ADL/IADL) items included toileting, dressing, transferring, bathing, eating, ambulation, and internal medicine use. Cognitive status was measured by the short, portable mental status questionnaire. The health section included self-reported health, vision, hearing, self-diagnosis, and health care utilization. For this study we added three questions to tap mood (depression, anxiety, and positive affect) and questions on activities, recent relationships, satisfaction items, and items on factors related to choice of care setting adapted from an earlier study of nursing home outcomes.[11] The questionnaire and the Oregon SSD 360 are available from the authors. The instrument was characterized by its use of direct questions to respondents rather than by interviewer ratings of the attributes of the respondents.

Statistical Analysis

All data analyzed were categorical. Crosstabs were run on all data with hierarchical loglinear three-way chi-squares used to judge whether the main effects of client setting or payment status or their interactions were significant. Logit analysis was performed to determine which factors predict care setting and payment status within care setting.

Findings

Case-Mix Differences

As shown in Table 1, the demographic characteristics of the samples were similar across care settings, with payment status in foster care reflecting actual proportions in the population. We have separated the private and Medicaid supported clients in all analyses because of policy interest. There were, however, some substantial differences between the two groups. Foster care residents were less likely to come from acute care hospitals. Only 12% and 13% of Medicaid and private pay residents were admitted from a hospital, compared with 44% and 33% of corresponding nursing home patients. Fourteen percent of Medicaid and 17% of private adult foster care residents came from nursing homes, whereas only 9% of Medicaid residents and 7% of private nursing home residents came from adult foster homes.

Table 2 contrasts the pattern of diagnoses. The residents in nursing homes had more major health problems than those in adult foster care; yet this information must be interpreted with some degree of caution because some adult foster care providers had imprecise knowledge of their clients' diagnoses, and the records in adult foster care homes were less complete than in nursing homes. There were also differences by payment status. These did not follow as clear a pattern. For example, whereas clients with dementia were more frequently private pay in adult foster care, they were about equally distributed in nursing homes at a rate still higher. By contrast, patients with seizures were more

TABLE 1—Demographic Background of Sample

SPMSQ = Short Portable Mental Status Questionnaire.

likely to be Medicaid clients in nursing homes and developmentally disabled clients were more likely to be supported by Medicaid in both settings.

The extent of dependency in ADLs is shown in Table 3. More adult foster care clients were able to perform each of the six ADLs studied without assistance. Private paying residents in adult foster care were more disabled than those supported by Medicaid, whereas the proportions were more similar within the nursing home sample. This pattern of difference by payment status is also seen in the levels of cognitive performance on the 10-item Short Portable Mental Status Questionnaire (SPMSQ[12]; see Table 4). Among adult foster care residents, 33% of the private-pay clients had five or more errors, and another 23% could not respond to the test at all. Among the Medicaid foster home group, 27% had five or more errors, and only 7% could not respond. In the nursing home sample, 43% of the private-pay clients made five or more errors, and 41% could not respond; for Medicaid residents the comparable figures were 36% and 36%. Thus a total of 56% of private-pay adult foster care residents and 34% of Medicaid residents did poorly on the SPMSQ compared with 84% of private pay nursing home residents and 72% of Medicaid residents.

TABLE 5—Proportion Considering Selected Factors Important in Selection of Care Setting

	Adult Foster Home, %		Nursing Home, %

Other	6	10	5	5
None of the above	—	—	2	1

[a]Respondents could select more than one factor as important.

Other reflections of the differences across these settings can be seen in the amount and location of physician care (not shown in a table). Although the proportion of clients reporting a physician visit in the previous 6 months was similar by payment status, nursing home patients were more likely to see a physician. Among adult foster care residents, 80% of Medicaid and 77% of private residents saw a doctor in the previous 6 months compared with 90% of Medicaid and 91% of private-pay nursing home patients. Caution should be used in interpreting these figures because physician contact is mandated on a periodic basis for Medicaid nursing home clients. The location of these visits was quite different. Whereas about 90% of the adult foster care residents saw a physician in his or her office,

AFC = adult foster care; NH = nursing home.

[a] Residents who did not need complete help on more than bathing (n = 290 in foster homes and n = 126 in nursing homes).

[b] Residents who need complete help with four or more functional activities (n = 54 in foster homes and n = 211 in nursing homes).

only about 30% of the nursing home patients did so.

Choice of Care Setting

Mostly, the preferences of those living in adult foster care were similar to those of nursing home residents. As shown in Table 5, however, there were some important differences. For example, adult foster home residents were more concerned about a homelike atmosphere and privacy, whereas the nursing home residents emphasized organized activities and physical rehabilitation. Not surprisingly, both groups valued safety and personal assistance. In choosing one setting over another, 60% of the foster care residents and 36% of the nursing home residents (or their family proxies) believed that they had at least some control over the choice of care setting. A nursing home had been considered by 20% of foster care residents and a foster home had been considered by 15% of nursing home residents.

[b] Residents who need complete help with four or more functional activities (n = 54 in foster homes and 211 in nursing homes).

Living Conditions

The differences in the two settings can also be seen in the way in which residents spent their time. Table 6 describes the residents' activities according to their level of functioning in their respective care settings. Better functioning adult foster care residents were more likely to watch television, talk with other residents, and help with cooking and housekeeping, whereas better functioning nursing home residents were more likely to participate in organized activities and games and listen to the radio. As shown in Table 7, adult foster care residents were more likely to leave the care setting for activities other than medical appointments, especially shopping and entertainment, a finding that held true when we controlled for functional status and for cognitive status. The reversal of the usual pattern for low functioning nursing home patients reflects the fact that nursing home staff is more likely to organize group activities or to bring activities to the residents. The patterns of responses in Table 8 suggest that adult foster care residents were less likely to get visitors than nursing home residents but more likely to have telephone contact. Nearly 25% of the nursing home residents compared with only about 10% of adult foster care residents had a visitor every day. Only about 5% to 10% of both groups had no visitors. Telephone access was more difficult in nursing homes. About 33% of adult foster care residents com-

pared with about 70% of nursing home residents had no telephone contact. Both cognitive and functional status was related to telephone access in both settings, but were less discriminating for visitors.

Satisfaction was generally high in both groups. Table 9 presents data on the reported satisfaction ratings for a number of items among the cognitively intact respondents. In general, the adult foster care respondents expressed stronger levels of satisfaction and less dissatisfaction. The exception to this pattern was in the area of safety of personal possessions where the adult foster care respondents showed greater degrees of dissatisfaction despite a larger proportion also being very satisfied.

Foster care residents and nursing home residents were similar in their use of hospitals in the past 6 months (18% for foster care compared with 15% for nursing home care) though the reported stays for foster care residents were, on average, 1.5 days longer (7.2 compared with 5.7). Foster care residents used emergency rooms more than did nursing home residents (20% compared with 8%).

Predicting Care Setting and Payment Status

We performed discriminant analysis on selected variables to identify which distinguished between adult foster care residents and nursing home residents and to predict payment status within each of the care settings. We have characterized the underlying care needs of our population with selected ADL and IADL variables: mobility, transferring, bathing, dressing, feeding, toileting, a summary score, and taking medicines. It was also hypothesized that a number of diagnoses would play a role in distinguishing between types of residents (residents with heart disease, skeletal-muscular problems, stroke, hip fracture, cancer, diabetes, incontinence, vision problems, hearing problems, and mental illness). To capture cognitive functioning, we included a variable for whether a proxy was used for the interview. We have also included five variables that describe where the client was living or from where he or she was admitted prior to coming to the setting: in a relative's home, in an adult foster home, in a residential care facility, in a nursing home, or from the hospital. Finally, we included two other demographic variables in the analysis: marital status and gender.

Table 10 shows that, of the functioning status variables, transferring, toileting, and taking medicines were significant in explaining the likelihood of a client's entering an adult foster home, whereas none predicted nursing home residency. Women were almost 19% more likely to be in adult foster homes. Residents who had previously lived in their family's home or other foster homes were 15% to 35% more likely to be in adult foster care. Only hip fractures and being on publicly subsidized care explained the likelihood of entering a nursing home.

Two variables, transferring and bathing, were important in estimating that an adult foster care resident is receiving Medicaid (see Table 11). In fact, residents needing help with transferring were more than 38% more likely to be in foster homes than in nursing homes. Marital status alone helped estimate clients with private sources of payment.

Table 12 shows that in a nursing home Medicaid payment status can be predicted by the presence of skeletal-muscular disease and the ability to take medicines. Privately paying residents, on the other hand, are more likely to be married, to have had cancer or a hip fracture as a diagnosis, and be incontinent.

By using hierarchical loglinear models to explain differences between care setting or payment status, we determined that none of our main effects or first level interactions was found to be significant.

Discussion

These data corroborate impressions that, although adult foster care serves many elderly people with disabilities, the two forms of care serve rather different groups of the frail elderly. The patterns of frailty overlap to a considerable degree, but adult foster care treats a population that is, on the average, less physically and cognitively dependent than that found in nursing homes. Part of this effect may be due to the displacement that has already occurred, but at least part of it corresponds to the care needs of two distinct groups, at least at the ends of the distributions. Private-pay residents in foster care, however, show more functional impairment and cognitive impairment than do the Medicaid residents, making implausible the contention that state policy was driving Medicaid residents to accept a lower level of care than they might choose. Because the study is cross-sectional, we cannot say whether this discrepancy is due to more impairment among private-paying clients at admission or to a lesser likelihood that the residents are discharged to a nursing home, or to both.

TABLE 10—Variables That Explain the Likelihood of a Person's Entering an Adult Foster Home[a]

	b	Significance	Percentage[b]
Being female	.79778	<.01	17.1
Having previously lived in relative's home	1.11529	.03	27.1

Being married	−1.1066	.03	−22.0

[a] This represents the percent change in the probability of an adult foster home resident's being supported by Medicaid rather than by private means when these residents have the specified characteristics.

It seems unlikely that adult foster care will replace nursing home care completely, and there will continue to be a need for both services. But adult foster care will probably continue to serve some (and perhaps a growing number) of persons who could also be legitimately served in nursing homes. Categorizing client needs in long-term care remains an imprecise activity, permitting a great deal of discretion in care planning. The policy issue becomes one of whether long-term care will be envisaged as a continuum with a niche for each client or whether it will be viewed as a repertoire of services that allows considerable choice based on lifestyle preferences and prices. A related policy issue cast in relief by this study is whether socially oriented care settings such as adult foster care in Oregon should be more heavily regulated to protect the residents at the risk perhaps of transforming the settings from homes to mini-nursing homes. This situation is exacerbated by the phenomenon of aging in place. Although the admission cohorts to the two forms of care may look more dissimilar, with time they grow increasingly to resemble each other and lead one to conclude that the care is interchangeable. It would, thus, appear both impractical and undesirable to formulate policies based on a rigid delineation of the "appropriateness" of the particular resident for the particular setting. It appears from our data that residents and their families at least in part shop for the setting that is "appropriate."

Moreover, adult foster care has proven attractive to the private market. It is important to appreciate that the growth of this sector in Oregon has not been the result of pressure from the Medicaid agency. Clients and their families able to choose the location of their care have opted for the greater privacy and ambiance and lower price of the adult foster home.

The apparent success of adult foster care has spawned concerns about the need for stricter regulation of this industry on a level more akin to that applied to nursing homes. This pressure is understandable, but it threatens the essence of the program; that is, an approach that relies on an extended family type of arrangement for most care and community agencies for the more technically sophisticated services.

From this cross-sectional study, it was impossible to examine change over time for residents in either care setting, although it appeared that, even when we controlled for disability, foster care residents enjoyed somewhat more social and community activity. In a forthcoming paper, we will compare change in functional outcomes for Medicaid foster care residents and nursing home residents, using the secondary data base available in the Medicaid program. The results of the present analyses offer support to those who are enthusiastic about the adult foster home as a viable option for some subset of those ordinarily served in nursing homes, while recognizing that on average the nursing home residents are more disabled. Indeed, the presence of the foster care program (and other home care programs not discussed in this paper) makes it likely that the nursing home population will be

International Workshop of Computing in Occupational and Environmental Health to Be Held in Paris in November 1991

The 3rd International Workshop of Computing in Occupational and Environmental Health will be held November 7 & 8, 1991, in Paris, France, at the Hotel Meridien-Porte Maillot.

Professionals in occupational and environmental health as well as computer scientists will compare their latest applications in the following areas:

- individual medical date records and process
- on-line or CD ROM databases development, particularly for bibliography and toxicology
- statistical and epidemiological applications
- management facilitations
- educational uses
- information and knowledge dissemination

As part of the meeting, an exhibition of services and equipment will be provided. For further information, please contact Maryke Lefebvre, SOPREP, 36 rue des Mathurins, 75008 Paris, France. Tel: 331/42.65.17.08.

Is Coronary-Care-Unit Admission Restricted for Elderly Patients? A Multicenter Study

Craig Fleming, MD, Ralph B. D'Agostino, PhD, and Harry P. Selker, MD, MSPH

ABSTRACT

Background. To investigate whether elderly patients are more likely to experience restricted access to high technology medical care, we examined the impact of age on the likelihood of coronary care unit (CCU) admission for patients with acute myocardial infarction.

Methods. As part of a prospective investigation of emergency room triage for patients with suspected cardiac ischemia, we studied 4223 patients presenting to six hospitals. Because CCU admission is the accepted standard of care for acute infarction, we defined nonadmission to the CCU as a restriction of access to care. We used a logistic regression model to control for gender, hospital, and CCU occupancy at the time of admission and examined the relationship between age and CCU nonadmission.

Results. Patients 75 years or older with acute myocardial infarction were 2.5 times more likely not to be admitted to the CCU than younger patients (RR 2.5, 95% CI 1.64, 3.85). Coronary unit admission was restricted even when the physician's admitting diagnosis was "myocardial infarction" (RR 7.1, 95% CI 2.1, 25.0) or "rule-out myocardial infarction" (RR 1.5, 95% CI 1.1, 2.1). Observed differences in clinical presentation or severity of illness between older and younger patients did not account for these findings.

Conclusion. Our findings suggest that physicians may intentionally restrict access to coronary care for elderly patients with acute myocardial infarction. (*Am J Public Health.* 1991;81:1121–1126)

Introduction

As health care expenditures continue to grow, concerns about the cost of medical care for the aged have arisen.[1,2] People over 75 years of age constitute the most rapidly growing segment of our population.[3] Because per capita costs of health care for the elderly exceed those of younger people, further increases in health care expenditures seem inevitable as our population ages. Intensive-care-unit (ICU) care, which accounts for a substantial portion of hospital-related outlays, is considered a prime target for limiting health care expenditures.[4]

In response to these concerns, society and the medical profession have begun to question the appropriateness of unrestricted use of high technology medical care in the elderly.[5–7] While there is presently no consensus regarding appropriate limitations of such care, it has been suggested that the threshold to admit patients to ICUs may already be age-related, resulting in less frequent admission of older patients despite more severe disease among the elderly.[8] To examine this issue, we studied the impact of age on physicians' coronary care unit (CCU) admitting practices for emergency room (ER) patients with symptoms suggesting acute cardiac ischemia. Our objective was to determine if differences existed in CCU admission practices for older patients, as compared with younger patients, that could not be attributed to differences in clinical presentation or severity of illness.

Methods

The data on which this study was based were collected prospectively during a multicenter clinical trial to study CCU admitting practices and to develop and test an instrument predicting the likelihood of acute ischemic heart disease among patients in the ER setting. More detailed information regarding the data collection and design of the study may be found in the paper describing that study.[9]

Participating Hospitals

The six participating hospitals in the study included two urban medical-school teaching centers, two medical school-affiliated teaching hospitals in smaller cities, and two rural nonteaching hospitals.

Study Subjects

The study included all consenting patients, 40 years of age and older, presenting to the ERs of any of the six hospitals, with a chief complaint of chest, jaw, or left arm pain, shortness of breath, or other symptoms suggestive of acute ischemic heart disease. These criteria were based on the Imminent Myocardial Infarction Rotterdam Study and identify more than 90 percent of patients with acute cardiac ischemia who seek medical care.[10] Patients were asked to participate in a study of the diagnosis and treatment of heart disease, and among patients meeting the entry criteria, 92 percent consented to par-

Relative risks are adjusted for admitting hospital and compare rates of CCU nonadmission for older age groups to those of patients in the 40–74 year age group.

ticipate in the study. Patients were enrolled during a 16-month period ending in August 1981. For the present study, we excluded all data collected during the experimental phase of our previous clinical trial of CCU use.[9]

Data Collection

Clinical data, cardiac-enzyme tests, and electrocardiograms (ECGs) were obtained at the time of entry for all consenting patients. Additional clinical data—including clinical records, follow-up ECGs, and cardiac-enzyme tests—were obtained for both hospitalized and nonhospitalized patients at 48 hours after admission. Mortality was determined from study inclusion through follow-up, including the index hospitalization for hospitalized patients. The overall follow-up rate was 89 percent.

Data Analysis

Study patients were stratified by age into a younger group (40–74 years) and an older group (75 years of age or older). Final diagnoses were assigned for each patient based on blinded review of the serial ECGs, results of the cardiac-enzyme tests, and the ER and hospital discharge records. Final "true" diagnoses of acute myocardial infarction or angina pectoris were based on clinical presentation, ECGs, and cardiac-enzyme tests using the World Health Organization[11] and New York Heart Association criteria.[12] We assigned final diagnoses on the basis of the patient's ER clinical presentation. Patients admitted to the hospital with other diagnoses, who subsequently had myocardial infarctions in hospital, were analyzed according to their initial diagnosis. For patients with acute myocardial infarction, clinical severity was stratified by Killip class at presentation.[13]

The probability of not being admitted to the CCU (i.e. CCU nonadmission) was the primary end-point of this study. For the purposes of this study, CCU care and ICU care are considered equivalent. "Step-down" Units were not included as CCU care because such units represent a less intensive standard of care. At the time of this study, CCU care was the accepted standard of care in the United States for patients with acute ischemic heart disease.[14] Hence, CCU nonadmission is considered to be an adverse event for patients with acute myocardial infarction.

Statistical Methods

All hypothesis tests were two-tailed. The hypothesis that physicians' CCU admitting practices were related to patient age (Table 1) was tested using a logistic regression model predicting the probability that the patient was not admitted to the CCU. Separate models were analyzed for each group of final verified diagnoses (acute myocardial infarction, angina pectoris and no acute ischemic heart disease). The factors included in each model were: age, gender, the hospital where the patient was evaluated (to control for differences in admitting rates among hospitals), and the occupancy level of the CCU at the time of the patient's admission. Patients over 75 years of age with acute myocardial infarction were also stratified by five-year age intervals (Table 2) and a similar logistic regression model was used to calculate age-specific relative risks for CCU nonadmission.[15]

The test for linear trends in proportions[16] was used to examine trends in CCU nonadmission rates for patients with myocardial infarction when stratified by Killip Class (Table 3). To test the hypothesis that differences in physicians' CCU admitting practices for patients with acute myocardial infarction were related to differences in clinical presentation between older and younger patients (Table 4), we used a multivariate logistic regression model predicting CCU nonadmission. The factors included in the model were: age, gender, the hospital where the patient was evaluated, presenting features, and separate interaction terms to detect relationships between age and each of the presenting features. The interaction terms were used to examine whether advanced age and the presence of a particular clinical sign or symptom had a significant impact on CCU nonadmission.

Tests for the observed differences in CCU nonadmission rates for patients on the basis of the ER physician's admitting diagnosis (Table 5) were performed using the Mantel-Haenszel Chi-square procedure to control for differences in hospital admitting rates.[17]

To examine the relationship between mortality and CCU nonadmission for older versus younger patients with acute myocardial infarction, we used a logistic regression model predicting mortality. The factors included in the model were: age, gender, the hospital where the patient was evaluated, CCU nonadmission and an interaction term for the relationship between age and CCU nonadmission. The interaction term was used to examine whether CCU nonadmission had a significant impact on the mortality of elderly patients with acute infarctions.

Results

The average sample size for the six hospitals was 704 patients and ranged from 453 to 938 patients. By hospital type, 1,505 patients were seen in the urban medical school teaching hospitals, 1,309 in the medical school-affiliated teaching hospitals in smaller cities, and 1,409 in the rural non-teaching hospitals.

The study included 3,225 patients (76 percent) ages 40 to 74 years, and 998 patients (24 percent) who were 75 years of age and older. The mean age was 58.9 years among the younger group of patients, and 81.0 years among the older patients. Male patients constituted 58 percent of the younger patients versus 41 percent of the older patients. Of all study patients presenting to the ER, 810 patients (19 percent) had acute myocardial infarction, 710 patients (17 percent) had angina pectoris, and 2,703 (64 percent) proved to have neither form of acute ischemia. No significant differences were found between younger and older study patients in the proportion of patients with acute myocardial infarction (19 percent in each group) or angina pectoris (18 percent vs 14 percent, respectively).

Although not presented here, the triage dispositions of patients 65–74 years of age did not significantly differ from those of younger patients, reinforcing the inclusion of this group with the middle-aged group. Age 75 years was selected as best representing a truly elderly group of patients, as noted in other discussions of health care for the elderly.[1,5]

Among ER patients who proved to have acute myocardial infarction (Table 1), CCU nonadmission occurred 2.50 times more frequently for patients 75 years of age or older than for patients 40 to 74 years of age (95% CI = 1.64, 3.85). Examination of the differences in CCU nonadmission rates among ER patients with acute myocardial infarction, stratified by five-year age intervals for older patients, shows that the likelihood of CCU nonadmission increases with advancing age (Table 2).

Among ER patients with angina pectoris (Table 1), the probability of CCU nonadmission for older patients compared to younger patients was less evident (RR 1.45, 95 percent CI = 0.98, 2.13). For patients without acute ischemic heart disease, CCU nonadmission rates for older and younger ER patients were not significantly different, although older ER patients were significantly less likely to be discharged to home from the ER than younger patients (RR 0.26, 95 percent CI = 0.21, 0.32).

Differences in the clinical severity of acute myocardial infarctions by Killip classes at the time of presentation for older and younger patients are shown in the first set of columns in Table 3. A clear trend towards an increasing proportion of more serious infarctions in older patients is seen. The second set of columns in Table 3 shows the differences in CCU nonadmission rates for older versus younger patients in each presenting Killip classes. For all presenting Killip classes, except Killip class 4, CCU nonadmission was more likely among older patients than younger patients. Among study patients with Killip class 4 myocardial infarctions, defined as presentation with cardiogenic shock, only one patient was not admitted to the CCU. The apparent trend towards increasing CCU nonadmission rates with advancing Killip class for older patients with Killip class 1, 2, and 3 myocardial infarctions is also clear.

To test the hypothesis that older patients with infarction were admitted to the CCU less frequently than younger patients due to less clearly diagnostic presenting signs and symptoms, we examined gender, ECG findings, and presenting complaints of chest pain, dyspnea, or other symptoms (Table 4). Two ECG findings indicative of acute ischemic cardiac disease, T-Wave peaking or inversion and ST-segment elevation or depression greater than 1 mm, increased the likelihood of CCU admission. Aside from age, only presentation with dyspnea and no chest pain predicted a decreased likelihood of CCU admission. We found no significant interactions in the regression equation between advanced age and any other presenting feature. Thus, older patients with any specific presenting feature were neither more nor less likely to be admitted to the CCU than younger patients with similar presentations. Furthermore, controlling for the effects of all of

TABLE 3—Distribution of Acute Myocardial Infarctions and CCU Nonadmission by Presenting Killip Classes among Younger and Older Emergency Room Patients (N = 810)

	Patients with Acute Myocardial Infarction n (%)		CCU Nonadmission for Patients in Each Killip Class n (%)	
Killip Class	Age 40–74 (n = 620)	Age ≥ 75* (n = 190)	Age 40–74 (n = 63)	Age ≥ 75** (n = 44)
1	429 (69)	80 (42)	48 (11)	14 (18)
2	107 (17)	47 (25)	9 (8)	11 (23)
3	62 (10)	48 (25)	5 (8)	19 (40)
4	22 (4)	15 (8)	1 (5)	0 (0)

*p < 0.0001 for trend of increased proportion of older patients with higher Killip classes.

**p < 0.0001 for trend of decreased CCU admission of older patients with higher Killip classes.

Percent of patients not admitted to the CCU are calculated relative to the numbers of patients in each age group within that Killip class.

TABLE 4—Multivariate Logistic Model of Presenting Features Associated with Nonadmission to the Coronary Care Unit Admission of Emergency Room Patients with Acute Myocardial Infarction (N = 810)

Presenting Feature (n)	Relative Risk for Nonadmission to the CCU RR (95% CI)
Age ≥ 75 (190)	2.4 (1.5, 3.8)
Male (503)	0.9 (0.5, 1.4)
Chest Pain in the ER (693)	1.6 (0.7, 4.0)
Both Dyspnea and Chest Pain (199)	1.1 (0.6, 1.9)
Dyspnea and No Chest Pain (78)	4.5 (1.8, 11.1)
No Dyspnea and No Chest Pain (56)	0.4 (0.1, 1.3)
ECG: T-Waves Peaked or Inverted (540)	0.5 (0.3, 0.7)
ECG: ST Elevation or Depression (681)	0.4 (0.2, 0.6)

No statistically significant interactions were found between age and other presenting features. NS—feature is not a significant predictor of difference in triage disposition at the p = 0.05 level.

TABLE 5—Triage Disposition for Younger and Older Emergency Room Patients by Emergency Room Physician's Admitting Diagnosis (N = 4,223)

	Emergency Room Patients with Each Diagnosis n		Patients with Each Diagnosis Not Admitted to the CCU n (%)	
Admitting Diagnosis	Age 40–74 (n = 3,225)	Age ≥ 75 (n = 998)	Age 40–74	Age ≥75
"Myocardial Infarction"	225	59	5 (2)	8 (14)
"Rule-out Myocardial Infarction"	1,116	294	223 (20)	79 (27)
All Other Diagnoses	1,854	645	1,502 (81)	497 (77)

Percentages of patients not admitted to the CCU are calculated relative to the numbers of patients in each age group with the diagnosis.

the presenting features on CCU nonadmission in a multivariate logistic model had no significant impact on the risk of age as an independent negative predictor of CCU admission.

To provide further support for the hypothesis that differences in triage disposition of elderly patients did not result simply from misdiagnosis, we examined the admitting diagnoses of the ER physicians to find whether differences in CCU admissions occurred for older and younger patients even when the ER physician believed the patient to have acute ischemic heart disease (Table 5). Among all ER patients with an admitting diagnosis of "myocardial infarction," 86 percent of patients 75 years or older were admitted to the CCU, compared with 98 percent of younger patients. Expressed as a relative risk, these older patients were 7.1 times more likely not to receive CCU care (95% CI = 2.1, 25.0). For ER patients with an admitting diagnosis of "rule-out myocardial infarction," older patients were 1.5 times more likely not to receive CCU care (95% CI = 1.1, 2.1). Further, upon review of the available 28 ER medical records for the 44 older patients with acute infarction not admitted to the CCU, there was no documentation that the patients themselves had requested a less intense level of care, or that they had impaired mental or social function.

Finally, did differences in triage disposition for older and younger patients have a measurable impact on mortality? Among all patients with diagnosed acute infarctions, mortality was greater for older patients than younger patients (29 vs 12 percent), but was similar among older patients admitted to the CCU versus those admitted to the wards or sent home (RR 1.12, 95% CI = 0.38, 3.7).

Discussion

The results of this study suggest that advanced age has an impact on the CCU admitting decisions made by physicians, most evident among ER patients with acute myocardial infarctions. None of the hospitals participating in this study had an explicit policy of rationing intensive care to elderly patients and lower CCU admission rates for older patients with acute infarction was not related to the occupancy level of the CCU. The observed difference in CCU admission rates for older patients with acute infarction did not result simply from diagnostic misclassification in the ER. Nevertheless, our data do not allow us to directly observe the reasoning or motivation underlying the triage decision.

Physicians' awareness that a study of CCU admitting practices was taking place may have affected our results even though physicians were not aware of the study hypothesis. Differences in the triage disposition of older and younger patients might have occurred if physicians improved their diagnostic accuracy more in younger patients than in older patients. However, this fails to explain why physicians, even when they had made a diagnosis of acute ischemic heart disease, as indicated by their admitting diagnosis of "myocardial infarction" or "rule-out myocardial infarction," were still less likely to admit an older patient to the CCU.

This study was primarily designed to examine differences in CCU admitting practices, and despite its size, its power to detect small differences in mortality and other outcomes among different subgroups of patients is limited. This is reflected by the fairly wide confidence intervals for the relative risk of mortality in older patients based on CCU admission. Because Killip classes are correlated with mortality,[13] the observation that among patients not admitted to the CCU, older patients had higher Killip classes of infarctions than younger patients suggests that differences in mortality may indeed exist.

Several factors not included in our data set may influence the ER physicians' decision not to admit elderly patients to the CCU. First, physicians may believe that CCU care for elderly patients is not cost-effective, particularly since unequivocal evidence demonstrating the efficacy of CCUs is lacking[18,19] and there is some evidence that medical intensive care is probably overutilized in the United States.[19] However, the differences in triage disposition we describe occur among patients with acute myocardial infarction, for whom CCU care is the present standard of care regardless of age. Thus, the notion that the physicians in our study were somehow utilizing CCU care more effectively for older than younger patients does not provide an appropriate explanation for our findings.

A second concern is that CCU care may be potentially harmful for older patients, because of the association between age and an increased likelihood of iatrogenic complications.[20] Thus, physicians may intentionally restrict CCU care for older patients for compassionate reasons.

Third, mentally competent patients, by exercising their acknowledged rights of self-determination, may themselves influence treatment decisions by refusing more intense levels of care.[21] However, review of available ER medical records for older patients with acute infarction in our study, who were not admitted to the CCU, yielded no evidence that patients themselves had influenced the admitting decision.

Fourth, socioeconomic factors may affect the level of intensity of care given to patients. For example, marital and insurance status have recently been shown to influence the choice of therapy for patients with lung cancer.[22]

Finally, it has been shown that the patient's capacity to interact meaningfully with others in established social roles influences physicians' decision making in the management of critically ill patients.[4] Thus, physicians might intentionally restrict CCU admission for elderly patients with dementia or severe disability. In our study, all participating patients were able to give informed consent and provide necessary information to the research assistants, so it is unlikely that dementia among older patients could account for the observed differences in CCU admission. Moreover, review of the available charts of elderly patients not admitted to the CCU, despite having admitting diagnoses of "myocardial infarction" or "rule-out myocardial infarction," yielded no evidence that such considerations played a role in this decision.

Several previous studies have examined the influence of age on ICU admission practices. In a study conducted at an urban hospital, it was noted that, although 10 percent of the general population age 75 years and older reside in nursing homes, only 5 percent of the ICU/CCU patients were nursing home residents.[23] In another study, the age distribution of patients receiving respiratory intensive care was found to be similar to the age distribution of the general hospital population, except for patients over 70 years of age, among whom there were fewer ICU admissions.[24] In a third study, examining selected patients admitted to the ICU and the general medical wards at the same hospital, no difference was found between the age distributions of ward patients and ICU patients, although there was a borderline significant higher severity of illness for older medical ward patients.[25] Overall, these studies, which looked at patterns of care at single institutions, provide indirect evidence of selective triage to ICU care for older patients.

This prospective multicenter study, following patients from their presentation in the ER, provides more direct evidence of restrictive use of intensive care for the elderly. If age influences the likelihood of ICU admission, then studying ICU patients alone, or even ICU along with ward patients, will introduce inclusion bias in study subject selection. To properly interpret data concerning the benefit or access to ICU care for elderly patients, it is important to study the "denominator" group of all patients seen in the emergency room who were candidates for ICU or ward admission, rather than "numerator" patients in one or two specific sites within the hospital.

The fact that the data for this study were collected between 1979 and 1981 might be considered a limitation to the usefulness of our findings. However, an advantage of these data is that they were collected prior to the advent of Medicare's prospective payment system. Provision of intensive care, a costly part of hospital care, is susceptible to PPS incentives,[4] which might confound a study of physician or CCU admission practices done more recently.

The data on which our findings are based also precede the widespread use of thrombolytic therapy for patients with acute myocardial infarctions. Most randomized trials of thrombolysis have excluded patients over the age of 70 because of fear of increased complications in the elderly.[26] If the availability of thrombolytic therapy creates an incentive to preferentially admit to the CCU those patients who receive thrombolysis, this may create another bias against CCU admission in elderly patients, particularly when limited CCU resources are available.[19] As hospital payment policy evolves and ongoing and planned trials of thrombolytic therapy that include aged patients are completed, these influences may be mitigated.

We have presented data suggesting that advanced age has an impact on the triage disposition of patients presenting with suspected acute ischemic heart disease that is not explained by differences in severity of illness or varying clinical presentations among older patients. While our findings are not definitive proof, they suggest that physicians may intentionally restrict access to coronary care for elderly patients. These findings should prompt further investigations to find consistent or countervailing evidence for elderly patients in other intensive care settings and with other conditions. ☐

Migrant Farm Workers in Need of Better Health Care

The Migrant Clinicians Network recently released the results of *Migrant Health Status: Profile of a Population With Complex Health Problems*, the first comprehensive investigation into health conditions for migrant and seasonal farm workers. Specific to those farm workers who migrate within the midwestern migratory stream, the study reveals an overall health status with higher rates of infectious disease than in the general population.

The results from this study are shocking. The demographic patterns, socioeconomic conditions, life-style characteristics, and disease categories reflect an agrarian society in a Third World country caught in an infectious disease cycle. Factors such as poverty, malnutrition, infectious and parasitic diseases, poor education, a young population, and poor housing equate to a highly vulnerable population in need of resources. Clearly, the migrant population is at greater risk and suffers more problems than the general population. The results of this research demonstrate the need for more service, care, and treatment. The need for developing a health policy and research agenda for migrant farm workers in this decade is evident.

The Migrant Clinicians Network (MCN) is a multidisciplinary organization of all health and human service professionals who work with migrant and seasonal farmworkers. The network was established in 1984 to identify and address clinical issues affecting the health status of the nation's migrant farmworker population. MCN comprises migrant clinicians from 41 states and Puerto Rico, representing a wide range of professional disciplines and areas of expertise. The Network serves as a clinical forum for migrant and seasonal farmworker health issues.

The health status study was conducted under the direction of G. E. Alan Dever, PhD, of Mercer University. For a copy of the executive summary, study monograph, or complete report contact the Migrant Clinicians Network, 2512 South IH35, Suite 220, Austin, TX 78704. Tel: 512/447-0770.

Comparison of Subjective Ratings of Function with Observed Functional Ability of Frail Older Persons

Janet T. Elam, BS, Marshall J. Graney, PhD, Terinell Beaver, MD, Douaa El Derwi, MD, William B. Applegate, MD, MPH and Stephen T. Miller, MD

ABSTRACT

Background. Important clinical decisions often hinge on patients' functional status. Previous studies have shown disagreement among sources of ratings of patients' functional status. This study compared patient self-ratings, family member ratings, and physician ratings of patient function to performance-based functional testing criteria.

Methods. Five activities of daily living of 73 older patients were studied at admission to a rehabilitation unit following discharge from an acute care community hospital. Data were collected from patients, family members, and physicians and were compared with performance-based function testing.

Results. Patient ratings were significantly more accurate than physician ratings for walking, transferring, and telephoning. Patients were significantly more accurate than family members for rating walking and telephoning, but patients were not significantly more accurate than family members or physicians for rating eating or dressing.

Conclusions. We conclude that decisions about patients' functional level should be based on performance testing. If performance testing is unavailable, patients' own ratings are most accurate, followed by family ratings. Physicians' ratings are least accurate. (*Am J Public Health.* 1991;81:1127–1130)

Introduction

Functional assessment of elderly patients has been a focus of research for more than 25 years.[1] Its importance is demonstrated by the one fifth of persons aged 65 and older in the United States who are unable to perform at least one measure of activities of daily living (ADL).[2] The complexity of functional measurement is demonstrated by more than 40 published ADL scales.[3] Most ADL scales use patient self-report to rate performance of tasks. Recently investigators have compared ADLs measured by an assessment instrument or geriatric evaluation to patient self-report, family report,[4] or physician report[5] and found that different sources of ADL rating may not agree and therefore are not interchangeable.

A recent review by Guralnik and colleagues[6] makes a strong case for the value of performance-based ADL measures. Elderly patients who experience an acute illness or injury often have decreased function requiring decisions ranging from assistance with personal care to permanent nursing home placement. During hospitalization patients may be unable to assess their own functional status because their activities may be medically limited. Thus, accurate assessments of function are needed to ensure appropriate recommendations. Because sources of ADL ratings may disagree, comparisons of different rating sources with objective measures of performance are important to characterize the accuracy of various rating sources.

This study was designed to evaluate performance-based ADL testing in a community hospital rehabilitation unit. Unlike previous studies, we compared the accuracy of self-ratings, family ratings, and physician ratings to performance-based measures.

Methods

Study Sample

Seventy-three patients aged 60 years and older were studied between January 1987 and March 1989. These patients had been hospitalized at the Baptist Memorial Hospital, a large community hospital, for acute medical or surgical problems and required additional rehabilitation.[7] Patients were eligible for enrollment in the study if they agreed to participate, signed informed consent, were cognitively able to participate (no more than four errors on the Short Portable Mental Status Questionnaire),[8] were not aphasic, and had a family member currently involved in their care. This was defined as a relative who visited the patient during the acute care hospital stay and was willing to assume responsibilities for assistance when the patient was discharged.

Measurement

Although the number of days of the acute hospital stay was not recorded, all

TABLE 1—Demographic and Functional Health Data (N = 73)

Variable	Data
Age (years)	
Mean ± SD	77.3 ± 7.9
Range	61–98
Sex (% female)	62.5
Race (% white)	87.7
Marital status (% married)	31.5
Baseline ADLs (% independent)[a]	
Walking	42.5
Transferring	52.8
Telephoning	77.5
Eating	93.1
Dressing	77.5

[a] Observed performance test data.

patients enrolled in the study were medically stable and ready for rehabilitation. As part of the initial evaluation at transfer to geriatric rehabilitation (usually the same day) patients were first asked to rate their abilities to walk, dress, eat, transfer, and use the telephone, using a standard format from the Framingham Disability Study.[9] Five performance levels were possible: (1) independence, (2) requires use of equipment, (3) requires assistance of another person, (4) requires assistance of another person and equipment, or (5) unable to perform. These same abilities were rated separately by the caregiving family member and by the patient's personal physician. At admission patients were also asked to perform five tests which corresponded to the five rated abilities: (1) walking; walk 25 feet; (2) dressing: button a shirt; (3) eating: transfer dried beans with a spoon from one dish to another; (4) transferring: transfer from bed to chair; and (5) telephoning: make a telephone call.

Interviews and performance-based testing were conducted by a nurse clinician or by one of two physician research fellows. Family members were interviewed at the rehabilitation unit or by telephone. All interviews with patients' personal physicians were made by telephone. Interviews with family members and physicians were made within 48 hours of the patient interview or considered unobtainable. Demographic information was collected from patient's medical records.

Patient interviews and observational protocols were completed for 73 patients. Sixty-four (88%) family member and 49 (67%) physician interviews were completed within 48 hours of the time patient data were collected. Complete observational, patient, family, and physician data collection protocols were executed for 41 (56%) patients. Data on observed ADL, age, sex, race, and marital status were analyzed to detect potential bias caused by some physicians' nonparticipation. No statistically significant differences in these variables were found between patients whose physicians participated and those whose physicians did not.

Data Analysis

Data were analyzed using the SPSS^{x} system of computer programs, including CONDESCRIPTIVE for descriptive statistics, CROSSTAB for truth tables, and PEARSON CORR for correlations.[10] The χ-square test was used to determine the independence of ratings vs the performance test criterion. Differences between these χ-square tests were used to test for differences in the agreements of ratings with the criterion. In all cases, $P<.05$ was used as the criterion of statistical significance. Significance levels were adjusted for multiple comparisons when appropriate through use of the Bonferroni method.[11]

For analysis of accuracy of ADL ratings the five levels of ability for each ADL were dichotomized as independent vs dependent. Independence was defined as performance of the ADL without assistance from another person, and dependence was defined as nonperformance or need for the assistance of another person to perform the ADL.

Actual performance ability, assessed by direct observational testing, served as the criterion of performance of an ADL. Criteria for evaluating diagnostic tests (including sensitivity, specificity, predictive value of a positive test, and predictive value of a negative test) were adopted to evaluate the accuracy of ratings by use of the analogy whereby functional dependence was equated with the presence of a disease condition, i.e., a positive test. Thus, sensitivity was defined as the number of patients rated dependent who also were observed to be dependent divided by the number observed to be dependent. Specificity was defined as the number of patients rated not dependent who also were observed to be not dependent divided by the number observed to be not dependent. Predictive value of rated positive was defined as the number rated and observed to be dependent divided by the number rated dependent. Predictive value of rated negative was defined as the number rated and observed to be not dependent divided by the number rated not dependent.

Results

Demographic and functional health data for the 73 study patients are presented in Table 1. Patients were transferred to rehabilitation with diagnoses representing all major rehabilitation groups. Twenty-four percent had a primary diagnosis of stroke, 17% had experienced fractures (of these 50% were hip fractures), 48% had a primary medical diagnosis, and 11% had other problems.

To investigate overall rater performance in accurately documenting patient ADL status, zero-order correlations of patient, family, and physician ratings for each ADL compared to observed performance are presented as phi coefficients in Table 2. For walking, the ratings of patient, family, and physician were all significantly correlated to observed performance. For transferring, telephoning, and dressing, both patient and family ratings were significantly correlated to observed performance. For eating, only patient ratings were significantly related to observed performance. Thus, patient ratings were significantly correlated to performance data for five of five ADL, family ratings for four of five, and physician ratings for one of five.

Other results comparing observed performance to patient, family, and physician ratings are also shown in Table 2. For walking and transferring, physician ratings have low specificity (walking=45%, transferring=38%) due to underestimation of the number of independent patients. Patient self-ratings ($P<.005$) and family ratings ($P<.005$) were both significantly more highly correlated to observed performance than were physician ratings for walking and transferring. In addition, patient self-ratings for walking were significantly more highly correlated to observed performance than were family ratings ($P<.005$).

For telephone use, physician ratings had low sensitivity (25%) because physicians rated too few patients as unable to use the telephone. Family raters also had difficulty with rating telephone use, and their underestimation of dependency was documented by the family raters' low predictive value of rated positive (42%). Patient self-ratings ($P<.005$) and family ratings ($P<.05$) were both significantly more highly correlated to observed performance than physician ratings for telephone use. As with walking, patient self-ratings of telephone use were also significantly more highly correlated to observed performance than family ratings were ($P<.005$).

For eating, patient, family, and physician too often rated patients as dependent, resulting in poor predictive values of rated positive. In addition, physician ratings lacked sensitivity, not detecting which patients were dependent in eating. All raters lacked specificity and showed poor predictive values of rated positive for dressing, chiefly because of underrating independent dressers.

Discussion

When an elderly patient has an acute illness or accident, decisions about the level of care required at hospital discharge can permanently alter the patient's living arrangement. Questions arise concerning need for postdischarge services such as home health care. Although on the one hand it is advisable to avoid inappropriate institutional placements, on the other hand patients living in the community who are too functionally dependent to care for themselves pose a burden for themselves and others.

How best to evaluate functional level is a question with which researchers have long struggled. Self-reported ADLs may include potential that the patient has not yet regained or represent performance that the patient may be unable to attain at the time of observation because of temporary physical status or environmental limitations. Our experience with performance testing supports the opinions of Guralnik et al.[6] that performance testing can be easily administered, is not overly time consuming, is well received by patients, and results in no harm to patients. Although we did not use the same tests, our methods for measuring function were similar to those described by Guralnik and colleagues. Also, the general agreement of patient and family ratings with observed function data validates performance testing.

Our data showed that patients and, to a lesser degree, family members had good knowledge of the patient's ability to walk, transfer, use the telephone, and dress. Also, patient ratings of eating ability were fairly accurate. By type of function, the predictive value of rated positive was highest for patient and family for the lower extremity skills, i.e., walking and transferring. For upper extremity skills the predictive value of rated positive was uniformly lower.

TABLE 2—Estimates of Predictive Accuracy

ADL and Rater	Sensitivity, %	Specificity, %	Predictive Value of Rated: Positive, %	Predictive Value of Rated: Negative, %	Correct, %	Phi Coefficients[a]
Walking						
Patient	90.5	90.3	92.7	87.5	90.4	0.80*
Family	83.3	67.9	76.9	76.0	76.6	0.52*

[a] Statistical tests of association between rater and performance data.
*$P < .001$.
**$P < .05$.
***$P < .005$.
****$P < .01$.

Physicians underestimated independence for lower extremity ADLs and overestimated independence of ADLs requiring cognitive skills, such as dressing and telephoning. These findings are in agreement with earlier findings of Pinholt et al.,[5] who found that mental status deficits were underreported in a comparison of ratings of residents, interns, and nurses to functional ratings by geriatricians using assessment instruments. Also, our finding that patient and family ratings were significantly different from each other for walking and telephone use agrees with findings published by Rubenstein et al.,[4] who observed significant ADL report differences between patient and family.[4] In the Rubenstein study, patients and family ratings were compared to ratings by nurses who provided daily patient care. This criterion differs from the criterion in our study, which was performance-based ADL testing. As in Rubinstein's study, our family raters underestimated independence in walking and transferring; however, in contrast to Ruberstein's results, our patient raters had the best overall accuracy. Our study differs from previous studies comparing clinical ADL rating to other rating sources in a fundamental way. Our physician raters were all community hospital based private practitioners, responsible for the patient's daily care during the acute care hospitalization. Most were internists who had a long-term relationship with the patient. This is in contrast to the Rubenstein study, which was set in a Department of Veterans Affairs Hospital,[4] and to the Pinholt study, which was set in a military hospital.[5]

This study represents an attempt to learn about the measurable components of ADLs. Choosing the optimum surrogate measure to use in performance testing is difficult, and some of the differences observed between performance testing and subjective ratings may be due to the fact that the performance measures do not assess all the complex aspects of a given ADL. Variables like walking and transferring can be observed directly. For other ADLs such as dressing and grooming, which require multiple functional and cognitive skills, choosing surrogates is more difficult. For example, our choice of shirt buttoning as a surrogate for dressing may not have been optimal because buttoning lacks representation of lower extremity dressing and does not represent the cognitive processes necessary to select clothing and to don garments in order.

This study has some limitations. Study patients were not representative of the entire population of acute care patients because all had family members involved in their care and all were eligible for rehabilitation. Demented patients may not report their function accurately and were excluded from our study. Our study did not observe continence and toileting, and these ADLs were not included in our ratings. Personal physicians were asked to answer immediately to our inquiry and were not given an opportunity to collect additional information from observations, patients, or family. However, they were the attending physicians during the hospitalization and had ample opportunity to collect these data. All study physicians practiced in a large community hospital in a metropolitan area. These results may not apply to other service settings and may not, for example, represent the situation in nonmetropolitan areas, where physicians might have a lifetime relationship with the patient.

In summary, physicians would be well advised to formulate recommendations that are dependent on function after obtaining objective measures of performance. If performance testing is unavailable, patient self-rating usually serves well for ADLs, especially those related to ambulation. For patients incapable of giving reliable ratings, family rating is the best substitute. If physicians would include questions concerning performance in these areas in their routine history-taking, their knowledge of their patients' performance might be improved. ☐

Acknowledgments

This paper was presented, in part, at the 42nd Annual Meeting of the Gerontological Society of America, November 17 to 20, 1989.

Call for Abstracts for APHA Late-Breaker Epidemiology Exchange Session

The Epidemiology Section will sponsor a Late-Breaker Epidemiology Exchange on Wednesday, November 13, 1991, at APHA's Annual Meeting in Atlanta. The exchange will provide a forum for presentation of investigations, studies, methods, which have been conceived, conducted, and/or concluded recently so that abstracts could not meet the deadline for submission to other epidemiology sessions. Papers submitted should report on work conducted during the last 6 to 12 months.

Abstracts should be limited to 200 words; no special form is required. Abstracts should be submitted to Robert A. Gunn, MD, Division of Field Epidemiology, Epidemiology Program Office, Mailstop C08, Centers for Disease Control, Atlanta, Goergia 30333 (Tel: 404/639-3661; FAX: 404/639-3950, and must be received by October 4, 1991). Receipt of abstract will be acknowledged by postcard and acceptance will be decided by October 9, 1991 (please include a return envelope).

Screening Recommendations for the Elderly

Mark H. Beers, MD, Arlene Fink, PhD, and John C. Beck, MD

ABSTRACT

Background. Studies have documented the potential contributions of preventive health care programs. Yet little is known about which screening tests should be included in public health programs for older persons. This study offers recommendations regarding these tests.

Methods. The recommendations come from synthesizing the findings of the US Preventive Services Task Force, the literature, and the consensus of experts in geriatrics, gerontology, and health policy research. The literature was evaluated to identify methodologically sound studies of the prevalence of selected disorders and benefits and availability of screening procedures for those disorders. Experts from various fields specializing in the care of the elderly formed panels to assist in evaluating the literature and providing further information from gerontological and public health perspectives.

Results. We recommend vision testing for refractive error; inspection of the skin surface for fungal infection and skin cancer, drug eruptions, and xerosis; a history for symptoms of xerosis; audiometric testing for presbycusis; surveys for hearing loss; otoscopic inspection for cerumen impaction; dental examination for caries; measurement of blood pressure for hypertension; and breast examination and mammography for cancer.

Conclusions. Our study suggests that these screening procedures are useful for public health screening programs. More information is needed on the effects of screening services on the health and functioning of older persons. (*Am J Public Health.* 1991;81:1131–1140)

Introduction

The American nation is growing older.[1] During the past two decades, the population over 65 has grown more than twice as quickly as the rest of the US population. In 1986, 41% of the elderly were 75 years of age and older; by the year 2000, half the elderly are expected to be over age 75. The 85-and-over population is growing especially rapidly. This group is expected to be seven times as large by the middle of the next century as it was in 1980. The number of functionally impaired elderly is already large and is expected to grow rapidly.[2] As the population ages and becomes more impaired, concern for the prevention of disease and promotion of good health increases.[3]

Studies have documented the potential contributions of preventive health care programs.[4] Advocates assert that preventive programs would result in a healthier and more industrious older population that could assist in reducing the nation's expenses for medical care and social support and contribute to the gross national product.[5] Investigators have documented a high prevalence of undetected, correctable medical conditions among older adults living in the community.[6] As many as 94% of elderly persons screened in a community program were found to have some positive finding requiring advice or information.[7]

Little information is available, however, regarding the screening tests that should be an integral component of a public health program for older persons. Unlike screening in office practice, public health programs do not focus on treatment but, instead, emphasize referrals and prevention. Many, like the California Preventive Health for the Aged Program, are publicly funded, use trained nurses, and are mobile, thus limiting their use of some screening equipment. Among the considerations for screening services for public health programs would be the accuracy of such tests in detecting prevalent, asymptomatic disease, the availability and appropriateness of use of screening, and the availability of beneficial treatment of the diseases that are discovered.

We synthesized findings from the literature, the US Preventive Services Task Force,[8,9] and experts in geriatrics, gerontology, and health policy research to identify screening services that are appropriate for public health programs conducted by nurses.

Methods

Data Sources

Expert Panels. We identified laboratory screening tests, periodic medical review, hypertension, mental health, dermatological problems, ophthalmological problems, dental problems, and hearing problems as areas of greatest concern. Using these as a starting point, we consulted with experts in geriatric medicine and gerontology to help us select specific topics (e.g., stool guaiacs as a laboratory screening test or glaucoma as an ophthalmological condition).

We assembled 24 members of UCLA's academic faculty and clinical ex-

This paper was submitted to the journal October 10, 1990, and accepted with revisions March 8, 1991.

perts into eight panels corresponding to the areas listed above. Panel members were selected for their knowledge of preventive health care and of the elderly. Panels ranged in size from four to six members, with at least one physician-member of UCLA's Multicampus Division of Geriatric Medicine and Gerontology and one health services researcher with expertise in geriatrics and consensus methods. Other members were expert in one or more of the study topics.

We adopted a two-round consensus method that has been used successfully to resolve issues of uncertainty in health care.[10,11] During the first round, panelists worked independently and without discussion to complete a written questionnaire. They sent the results for synthesis and then met to discuss the findings. Areas of agreement and disagreement were discussed, with the major emphasis on resolution of disagreements. After discussion, the panelists rerated each question.

Literature Review. Our review included studies that were published in English between 1978 and January 1989. We relied on a selective list of investigations considered by experts to be important in guiding geriatric health care practice rather than striving for a review of all published studies.

Inclusion criteria. The purpose of the literature review was to synthesize current knowledge from methodologically sound studies regarding the incidence and prevalence of selected undetected disorders in the elderly and the effectiveness of screening and early treatment. By screening, we meant any methods of detecting disease, regardless of stage or severity; prevention meant primary and secondary measures. Tertiary prevention was not considered in this project. The methods of screening included physical examination and history; patient questionnaires; instruments such as the sigmoidoscope and ophthalmoscope; and laboratory tests such as fasting glucose and thyroid function tests.

Exclusion criteria. We did not review essays or methodologic studies (e.g., to determine the psychometric properties of a measure of function or mental status), although we examined their reference lists for data sources appropriate to our review. We did not include articles whose main purposes were to investigate the treatments and outcomes of care unrelated to screening. We excluded review articles, except in the case of hypertension, because the results of research had been extensively synthesized.

Sources of information. We identified literature through several mechanisms. All members of the expert panels recommended research studies on screening, and references in those papers were also reviewed. We conducted a MEDLINE search simultaneously.

Abstraction of information. We reviewed all articles suggested by the project members, located through secondary sources, or uncovered by the computerized search (see Appendix A), but we abstracted only those that met our inclusion criteria (see Appendix B). We developed an abstraction form for recording the contents of each article. Ten articles were reviewed by three members of the team to establish the reliability of the abstraction process. We focused on the extent to which the inclusion and exclusion criteria discriminated among articles and whether agreement existed on their contents. When we were satisfied with the form's capability to facilitate consistent results, we each reviewed articles; every fifth article received a second review to ensure the continued uniformity of the abstraction process.

Evaluation of the literature. The literature was evaluated on the basis of the quality of the research design using methods similar to those of the Canadian Task Force on the Periodic Health Examination,[12] the US Preventive Services Task Force,[8] and the RAND/UCLA Variations Study.[13] The best evaluations were assigned to studies with the most rigorous designs (e.g., randomized, controlled trials). Only studies that provided convincing evidence through methodological rigor (e.g., controlled studies) were deemed acceptable.

US Preventive Services Task Force. The results of the US Preventive Services Task Force became available in 1989. The credentials of the Task Force panel members and the methods used to arrive at recommendations are described elsewhere.[8] Our study could not rely solely on the results of the Task Force for three reasons. First, the panelists did not explore all the topics in which we were interested, such as functional assessment. Second, although some Task Force recommendations directly affect older persons, the elderly are not the primary focus, and no geriatricians served on the Task Force's 20-member panel. There are many topics, such as the evaluation of dementia or the prevention of functional impairment, for which the perspective of geriatricians and gerontologists may differ from that of other clinicians and researchers. The third reason for not relying solely on the Task Force is that we were interested in public health programs rather than case management by clinicians. The Task Force addressed some diseases that occur almost exlusively in the elderly, such as glaucoma, and it also made specific recommendations for the elderly regarding hearing impairment and bacteriuria. This information was used as a major source of data in this study.

The Synthesis of Data

Our final recommendation for each topic is based on all data sources from which information was available. We assumed that a screening test should receive the highest recommendation if its use is supported by the literature and the US Preventive Services Task Force, it is not currently used appropriately, and it can effectively uncover prevalent, undetected disease for which beneficial treatment is available.

Throughout this project, we used the risk-benefit definition of appropriateness, meaning that a screen is appropriate when its potential benefit outweighs its potential risks. We based our assessment on the effectiveness of screening tests, i.e., the benefit for a given medical problem under average conditions of use.[14]

In this project, available meant that no barriers (such as lack of coverage by Medicare or scarcity of personnel or equipment) existed to prevent patients from receiving a test or treatment. We also included attention to compliance in our definition of availability because patients might not avail themselves of tests or treatments (e.g., hearing aids) if a social stigma or extreme discomfort were associated with them. By prevalent, we meant that the disease or condition occurred in a high enough percentage of elderly persons to warrant screening. We defined undetected disease as a disease or condition that is unknown to the patient or his or her doctor. A test or treatment was determined to be appropriate if those people who should be receiving it were receiving it. We called a treatment beneficial if it could help a substantial proportion of persons with the disease or condition while harming relatively few.

To arrive at our recommendations, we scored each topic (e.g., dental caries, screening for diabetes) on seven items: (1) extent of support from the US Preventive Services Task Force; (2) extent of support from the consultant experts; (3) extent of support from the literature; (4) prevalence of asymptomatic disease associated with the topic; (5) benefit of treatment for the disease; (6) current availability of treatment; and (7) current use of screening. We used a 9-point scale, with 1 = strongly negative (i.e., low prevalence, and little or no support, benefit, or availability), 5 = equivocal (i.e., average, neutral, or uncertain support, prevalence, or availability), and 9 = strongly positive (i.e., high prevalence, and much support, benefit, and availability). The final score for each topic was the mathematical average of ratings on all seven items. The strength of our recommendations is based on this final score according to the following scale. 9 = strongly recommended, 8 = recommended, 7 = recommended with reservation, 6 = equivocal, 5 = equivocal, 4 = equivocal, 3 = not recommended with reservation, 2 = not recommended, 1 = strongly not recommended. For example, a particular screening test might be strongly recommended by the US Task Force (9), and strongly recommended by the UCLA experts (9), although there is little or no literature supporting its use (5). The disease might be common, occurring in over 10% of the population (8). Moderately effective treatment (7) might exist, but the availability of that treatment might be limited due to its high price that is not reimbursed under Medicare and the reluctance of many individuals to undergo the treatment (2). Without new programs to encourage use of this screening procedure, it might be unavailable currently to most elderly persons (8). Such a scenario would receive a final score of 6.9, which we would round off to 7. We support the use of tests that score 7 or better; tests scoring between 4 and 6 are equivocal; and tests scoring between 1 and 3 are not recommended.

Results

Data Sources

Expert Panels. Topics discussed by the panels and their opinions follow.

Hearing

Hearing loss is extremely common in late life, affecting 25% to 35% of older persons, and it increases dramatically with advancing age. Mild hearing loss is more likely to be undetected. The most common causes of hearing loss in late life are presbycusis, cerumen impaction, and noise-induced sensory neuronal hearing loss. The best screening test for presbycusis and noise-induced hearing loss is pure-tone audiometry; the best screening test for cerumen impaction is otoscopic visualization of the auditory canal. Beneficial treatment exists for all three causes of hearing loss, although amplification is sometimes less successful for noise-induced hearing loss than for presbycusis. The use of amplification is limited because of its cost and the social stigma associated with using hearing aids.

Laboratory screening tests

Approximately 2% to 3% of elderly persons have undetected disease that can be diagnosed by routine laboratory tests. The most common undetected diseases (and the best screening methods for detecting each) are anemia (hematocrit or hemoglobin), bacteriuria (urinalysis), hyperlipidemia (serum cholesterol), diabetes (fasting blood sugar), bleeding colonic lesions (stool guaiac), hypothyroidism (TSH), and electrolyte disturbances caused by diuretics and nonsteroidal anti-inflammatory agents (serum electrolytes).

Beneficial treatments exist for hypothyroidism, bleeding colonic lesions (including early cancer), diabetes, and iatrogenic electrolyte disturbances. The benefits of treating anemia depend on the cause. The benefits of treating hypercholesterolemia probably depend on the age of the patient: treating elevated cholesterol in the very old may not be appropriate. Treating asymptomatic bacteriuria is probably beneficial in men but not in women. There is some limitation to the availability of treatment of diabetes due to the cost of medications and monitoring equipment and compliance with diet, medications, and monitoring. Treatment is limited for iatrogenic complications of medication use because physicians are often reluctant to change medical therapy on the advice of nonphysicians or because medical conditions necessitate their continued use. Hyperlipidemia treatment is limited due to the cost and side-effects of medication and compliance with dietary restrictions and exercise programs.

Periodic medical review

Over 50% of the elderly have some undetected disease or condition. The percentage that could be detected through medical history and limited physical examination could not be determined; however, the most common undetected diseases and conditions (and the best screening method for detecting each) that are likely to be found through periodic review are colon cancer (stool guaiacs), breast cancer (breast examination and mammography), coronary artery disease (history), urinary incontinence (history), inappropriate use of medication (medication review), impaired social functioning (screening scales), impaired physical functioning (screening scales), falls (history), and nutritional problems (weight and height). In almost all cases, these tests and procedures are either not currently available to the majority of elderly persons or are not used appropriately at the current time.

Beneficial treatment exists for early colon cancer, early breast cancer, and coronary artery disease. Treatments for the other diseases and conditions are limited at best, and, in some cases, attempts at treatment may be harmful. Treatment availability is limited for urinary incontinence, correcting inappropriate use of medication, and improving poor social and physical functioning, nutritional problems, and falls.

Ophthalmological disorders

Approximately 10% of elderly persons have undetected eye disease or visual impairment, and the prevalence increases with age. The most common diseases and conditions are glaucoma, cataracts, macular degeneration, and uncorrected refractive error; the oldest-old (persons over 85) are most likely to suffer from macular degeneration.

The panel suggested that when screening is performed by nonophthalmologists or nurses, tonometry is the best screening for glaucoma because it is inexpensive, administration takes minimal training, and expensive or bulky equipment is not required. Testing visual acuity is the best screening procedure for all of the other diseases mentioned. Persons with impaired visual acuity should be referred to an eye specialist for futher evaluation. The minimal barriers to obtaining these procedures are mostly due to lack of reimbursement by some Medicaid programs. Visual acuity testing is generally used appropriately, but tonometry is generally not.

The treatment for glaucoma is generally available and beneficial; treatment for cataracts is available and beneficial; treatment for macular degeneration is not beneficial and, if laser treatment is performed inappropriately or incorrectly, may be harmful; treatment for uncorrected refractive error is beneficial and generally available, limited only by cost and reimbursement.

Mental health

Depression can be defined by strict criteria as stated in the DSM-III-R[15] or by a looser definition of affective disorder serious enough to impact on functioning and well-being. Using the strict definition, 1% to 3% of elderly persons suffer from unrecognized depression, but using the looser definition, 7% to 11% are affected. Few data are available on either the best methods for screening for depression in the elderly or the accuracy of the screening. The panel suggested that the eight-item Medical Outcome Study scale[16] might be useful, especially if followed by the Diagnostic Interview Schedule[17], screening version. The CES-D[18] or Zung[19] scales might be useful alternatives. None of these screening tests is available or used appropriately at this time. Treatment of depression is beneficial, although its availability is limited by toxic side-effects of medication and lack of resources for counseling and other psychological therapies.

Nearly 4% of the elderly suffer from unrecognized dementia or chronic cognitive impairment, although we recognize that in some populations the prevalence may be higher.[20] The prevalence of these conditions increases with age. The panel suggested that the Folstein Mini-Mental State[21] is the best screening procedure, although this is only useful in English-speaking populations. Although these tests are available, they are not currently used appropriately.

Currently no good treatment is available for 80% of elderly persons suffering from cognitive decline; the remaining 20% may be helped by treating reversible illness, including depression. The availability and benefit of treatment are highly dependent on the exact cause and could not be estimated overall.

Dermatological disorders

More than half of elderly persons have undetected dermatological disorders severe enough to lead to complications or complaints, with a higher incidence in sunny states such as California. The percentage of undetected disorders that do not result in the seeking of care could not be estimated. The most common diseases and conditions in this category are fungal infections, skin cancer, drug eruptions, photoaging, and xerosis. Visual inspection by a trained observer is the best screening procedure, although a history of symptoms of dry skin is also important for finding cases of xerosis.

[b] Only review articles were included. See text for references.

Treatments for fungal infections, skin cancer, drug eruptions, and xerosis are both available and beneficial. The treatment of photoaging is probably not beneficial and generally not available, due to the cost of the medications and side-effects such as excessive skin dryness and pruritus.

Dental disorders

Nearly 50% of the elderly have undetected dental disease. The prevalence of undetected disease is likely to be highest for those with impaired mobility or limited finances. The most common diseases and conditions are caries, advanced gingivitis and periodontitis, xerostomia, and oral lesions including oral cancer. Clinical examination is the best screening procedure in all cases.

Beneficial treatments exist for caries, and, with certain limitations, for periodontitis, xerostomia, and oral lesions. The benefit of treatment of oral lesions depends on its characteristics. Treatment is available for each condition, although the availability of treatment for xerostomia is somewhat limited.

Literature Review. We reviewed 139 studies, 33 of which met our criteria for abstraction. We reviewed five pertaining to ophthalmology and three on periodic review of medical care but did not abstract data from them because they failed to meet our criteria. For most topics, the literature contributed limited data or no data at all.

Table 1 is a complete list of topics studied and the articles abstracted. Our review of the published literature disclosed a paucity of data on the effectiveness of screening. About two thirds of studies focused on the incidence and prevalence of disease, and the remainder emphasized the effectiveness of screening tests. Half the studies were supported by federal sources and one quarter used data collected between 1980 and 1983. In the 16 (48%) studies that specified duration, ten (33%) collected data for less than 2 years.

Most studies relied on local samples rather than statewide or national groups. Seven assessed randomly chosen samples, but none of these was a randomized controlled trial. Approximately 40% used physical examinations as the main source of data. More than half analyzed findings in terms of the age of the sample, and about half focused exclusively on the elderly. In 22 (66%) studies, participants were White.

Ten important review articles were identified that had examined the subject of screening for hypertension in the elderly.[22–31] Hypertension has been established as a risk factor for many serious problems, such as stroke, coronary artery disease, congestive heart failure, and multi-infarct dementia. Although some controversy still remains as to whether treating isolated systolic hypertension decreases mortality and morbidity, the general consensus is that treating both systolic and diastolic hypertension are useful and that detecting asymptomatic hypertension in the elderly is advantageous.

US Preventive Services Task Force. The Task Force provided data on 13 of this study's 34 specific topics. In some cases, the Task Force addressed issues that affect the elderly, but it did not specifically address whether screening needs were different in elderly populations. For four topics (hearing impairment, bacteriuria, elevated cholesterol, and visual acuity), the Task Force did specifically address the elderly, and in another three topics (glaucoma, dementia, and oral cancer), it reviewed topics that affect the elderly almost exclusively, although it did not specifically comment on the elderly. The Task Force recommended screening for hearing loss, elevated cholesterol, and loss of visual acuity.

Recommendations

Table 2 describes this study's recommendations and the bases on which they were made. We recommend the following without reservation: vision testing for refractive error; inspection of the skin surface for fungal infection, skin cancer, drug eruptions, and xerosis; interview for history of xerosis symptoms; audiometric testing for presbycusis and survey scales for hearing loss; otoscopic inspection for cerumen impaction; dental examination for caries; measurement of blood pressure

TABLE 2—Recommendations

Note: PR = disease prevalence; LT = literature review; PN = recommendations of panels; RXB = treatment benefit; RXA = treatment availability; SC = current availability of screening; TF = US Preventive Services Task Force. − = negative support; <> = equivocal support or no data; + = supportive data; ++ = strongly supportive data.

[a] 9 = Strongly recommended; 8 = Recommended; 7 = Recommended with reservation; 6 = Equivocal; 5 = Equivocal; 4 = Equivocal; 3 = Not recommended with reservation, 2 = Not recommended; 1 = Strongly not recommended. The prevalence of disease was estimated by panelists when data were not available. The benefits and availability of treatment and the current availability of treatment were rated by panelists.

for hypertension; and breast examination and mammography for cancer.

Discussion

The recommendations presented here are applicable to public health screening programs that aim to refer large numbers of community-dwelling elders and rely on nurses who often travel to deliver services. This study focused on screening for programs staffed by public health nurses, so some tests receiving low ratings might be appropriate for programs relying on physicians. The ophthalmoscope, for example, is an effective screening device for glaucoma when used by a trained ophthalmologist.

From the perspective of clinical geriatrics, many of the tests and procedures that are not supported by this study may still be appropriate when performed by physicians and other health professionals and used for purposes other than screening. Recording mental status, for example, may provide useful baseline data for determining changes in mental status. Also, asking about symptoms of depression, which are often missed by primary care practitioners,[32] is generallly considered important in primary care geriatric medicine. Measuring renal function with serum creatine may also result in useful baseline data, and following serum electrolytes can be useful in persons on medications, such as nonsteroidal anti-inflammatory drugs, when renal function is known to be impaired. Reviewing medication use is almost certainly important in geriatric care when performed by a primary care physician, although screening for inappropriate medication use by others cannot be supported by our research. Thus, recommendations made here for the exclusion of certain measures from screening programs should not be interpreted to mean that these measures should be excluded from good clinical geriatric care.

We limited our investigation of screening to eight broadly defined topics, and these do not encompass all the needs of the elderly. We did not explore screening for vaccination status, for example, or for review of gastrointestinal problems or joint disease. A complete screening package might require other procedures or questions not discussed here. Moreover, the information on which we based our recommendations may change at any time. New research or alterations in reimbursement policies for hearing aids or dental work, for example, would necessitate changes in our ratings. If changes in reimbursement policies were to make hearing aids available to more persons, our ratings for audiometry would move from recommended with reservation to recommended or strongly recommended.

Better data are needed to guide screening programs, and research is needed on such topics as the response of patients and physicians to referrals from screening programs and their outcomes. We need, for example, to determine whether depression screening scales can be used efficiently and accurately in a population of elderly persons, whether physicians are responsive to referrals about depression, and whether patients receive beneficial treatments sooner because of screening. Research is also needed on ways to get patients to use their medications correctly. If inappropriate use (including noncompliance with therapy, use of interacting drugs, or use of drugs that might impair function or cognition) is uncovered, what should be done to alter patients' and physicians' behavior? In fact, additional research on screening is needed for each of the topics explored in this study.

We urge cautious confidence in applying our recommendations. Despite their limitations, they represent the best possible efforts of some leading experts in geriatric health care to weigh scientific and experimental evidence. It is obvious from this investigation, however, that more information is sorely needed to strengthen the foundation on which health policy on screening in the elderly can be established. ☐

Acknowledgments

This project was supported by a contract from the California Department of Public Health.

The authors are most grateful to Ms. Rhoda Slagel, of the California Preventive Health for the Aged Program. We are also indebted to Ms. Nancy Marr for assistance in conducting the literature review, assembling the bibliography, and scheduling the panels and to Ms. Ana Shiwoku for assistance in preparation of the manuscript and organization of the project.

The Increasing Supply of Physicians in US Urban and Rural Areas, 1975 to 1988

Paul D. Frenzen, PhD

ABSTRACT

Background. Despite the rapid growth of the US physician supply since the mid-1970s, it remains unclear whether physicians have spread into the most rural areas of the country. This report examines the urban–rural distribution of physicians between 1975 and 1988.

Methods. A county-based typology of the urban–rural continuum was employed to examine trends in the supply of nonfederal primary care physicians, specialist physicians, and osteopaths.

Results. All urban and rural areas gained physicians during the late 1970s and 1980s. The supply of physicians increased most rapidly in metropolitan counties. Within nonmetropolitan areas, urbanized remote counties became more prominent centers of the physician supply. Osteopaths were more likely to locate in the most rural areas than allopaths. The physician supply in all areas also became more specialized over time.

Conclusions. The rapid growth of the US physician supply was associated with the spread of more practitioners into all parts of the country. However, the supply of physicians increased most rapidly in urban areas, widening urban–rural differences in the availability of physicians. (*Am J Public Health.* 1991; 81:1141–1147)

Introduction

The number of nonfederal allopathic and osteopathic physicians in the United States increased nearly four times more rapidly than the population between 1975 and 1988. Despite the rapid increase, physicians remained concentrated in urban centers. By 1988 the ratio of physicians per 100 000 persons was 226 in metropolitan areas and only 98 in nonmetropolitan areas. This gap has persisted despite government efforts to place more physicians in rural communities and concerns about an imminent national surplus of physicians.

The uneven distribution of physicians is partly due to the concentration of medical education, research, and specialized care in urban central places. However, there is much evidence that physicians prefer urban locations for other reasons, including the personal ties developed during medical training, the greater opportunities to interact with professional colleagues, and a taste for urban amenities.[1] The disproportionate tendency of physicians to locate in urban areas narrows the choice of practitioners for rural populations and suggests that physician services are relatively less accessible in rural areas.

The federal government first began to address the geographic maldistribution of physicians during the early 1970s, when a variety of measures were enacted to increase the supply of practitioners in inner cities and rural areas.[2,3] One of the most important measures was the National Health Service Corps (NHSC) scholarship program, which provided financial aid to medical students and other health trainees in return for service after graduation in designated Health Personnel Shortage Areas (HPSAs, formerly termed Health Manpower Shortage Areas).

Federal efforts to increase the number of physicians in underserved areas were curtailed during the early 1980s, and the NHSC scholarship program was gradually phased out.[2,4] The shift in policy was influenced by the 1980 report by the Graduate Medical Education National Advisory Committee (GMENAC), which predicted that a substantial surplus of physicians would emerge by 1990.[5] Federal officials also contended that market forces alone would be sufficient to attract more physicians to rural areas as competition intensified among physicians in urban centers.[2]

A series of studies by the RAND Corporation during the early 1980s provided evidence that physicians' location decisions had been affected by market forces.[6–10] The studies showed that the proportion of small towns served by various kinds of specialists had increased during the 1970s until nearly every urban place with 2500 or more inhabitants had at least one physician. The RAND researchers argued that physicians had responded to the increasing physician supply in accordance with economic location theory by diffusing to smaller places until all towns above a critical size had at least one physician. They also predicted that physicians would spread more widely in rural

This paper was submitted to the journal December 26, 1990, and accepted with revisions April 23, 1991.

areas during the 1980s as the growth of the physician population continued.[7]

In contrast, trends in physician/population ratios during the 1970s and early 1980s led other observers to conclude that physicians had not spread into rural areas in substantial numbers.[11–14] Metropolitan (metro) counties continued to have much higher physician/population ratios than nonmetropolitan (nonmetro) counties. Thus, physicians remained concentrated in urban centers. Further classification of counties by population size also showed that physican/population ratios had increased most slowly in small nonmetro counties. This trend was interpreted as evidence that few physicians had moved into the most rural areas of the country.[11,13]

Continued public concern about physician shortages led to new federal initiatives to place physicians in underserved communities during the late 1980s, including the NHSC loan repayment program and a Medicare reimbursement bonus for services performed by physicians in designated HPSAs.[4] Funding for the NHSC scholarship program was also significantly increased starting in 1991.[15] The new initiatives reveal that some areas remained unattractive to physicians despite the rapid growth of the physician supply.

The purpose of this report is to examine the growth of the nonfederal physician supply since the mid-1970s during a period of major changes in federal health personnel policy. A county-based typology of the urban–rural continuum will be employed to determine whether the supply of physicians increased in predominantly rural areas without sizeable towns, as well as in urbanized rural areas and smaller and larger metro centers. These distinctions are important because the RAND studies demonstrated that town size plays a critical role in physicians' location decisions. Other studies of the physician supply based on the classification of counties by population size have failed to identify predominantly rural areas because nonmetro counties with small populations may lie near metro centers or contain relatively large urban places.

Methods

Information about the annual distribution of patient care allopaths (MD physicians) and active osteopaths (DO physicians) by county was obtained from the 1989 Area Resource File and the 1975 to 1988 MD/DO Enhanced County File prepared by the Office of Data Analysis and Management, US Department of Health and Human Services. The data for allopaths and osteopaths were not always available for the same year. Federal physicians were excluded because most served special populations. Alaska was also excluded because the physician data for the state were not broken down by county. Additional information about the distribution of the resident population by county was obtained from the US Bureau of the Census intercensal population estimates. Counties affected by border changes between 1975 and 1988 were combined into larger units with constant boundaries.

Nonfederal allopaths were divided into two groups according to self-designated practice specialty: (1) primary care physicians providing patient care in general/family practice, internal medicine, obstetrics/gynecology, or pediatrics; and (2) specialist physicians providing patient care in any other specialty. Nonfederal active osteopaths were combined in a third category. Resident physicians were included in the appropriate category because they provided a substantial amount of patient care. Internal medicine subspecialist physicians were placed in the primary care category because they could not be distinguished from general internists prior to 1986. The small proportion of physicians who did not report a specialty were excluded from the analysis. Active osteopaths included both patient care and non–patient care physicians because the two groups could not be distinguished after 1981, when nearly 95% were engaged in patient care.

All counties were classified into 10 urban–rural continuum categories by using a typology developed by the Economic Research Service, US Department of Agriculture.[16] Counties were first divided into metro and nonmetro areas by using the 1983 US Office of Management and Budget definition of Metropolitan Statistical Areas (MSAs). Metro counties were then subdivided by 1980 MSA population and structure, and nonmetro counties were subdivided by 1980 county urban population and proximity to MSAs (Table 1). Variations in the level of urban influence are thus measured by the population and structure of MSAs in metro areas and by county urban populations and proximity to MSAs in nonmetro areas. Counties toward the urban end of the continuum are described as "more urban" and those toward the rural end are described as "more rural" for convenience.

The supply of physicians in each category was measured by the ratio of physicians per 100 000 residents. Separate ratios were calculated for primary care and specialist physicians for 1975, 1981, and 1988, and for osteopaths for 1976, 1981, and 1987. Since the reporting date for physicians shifted from December 31 to January 1 in 1988, the 1988 ratios were based on the 1987 resident population to increase comparability over time. The 1981 to 1988 period was only 1 day longer than the 1975 to 1981 period because of the shift in dates.

Changes in the physician supply over time were measured by calculating the mean annual change in the physician/population ratios for each urban–rural continuum category. This measure of absolute change was chosen to compare areas with different initial ratios.

Results

Primary Care Physicians

The total number of primary care physicians grew 3.8% per year between 1975 and 1988, rising from 132 000 to 207 700. During the same period the overall ratio of primary care physicians per 100 000 persons increased from 61.4 to 85.5 (Table 2). However, the ratio was substantially higher at the more urban end of the urban–rural continuum than at the more rural end (Figure 1). The central areas of large MSAs (large metro core counties) had the highest ratio throughout the period. The suburbs of large MSAs (large metro fringe counties) and medium metro counties had the next highest ratios. Small metro counties had lower ratios than other metro counties, but higher ratios than nonmetro counties.

Within nonmetro areas, urbanized counties had higher primary care ratios than less urbanized or rural counties. However, within each urban population category, remote counties some distance from MSAs had more primary care physicians than adjacent counties near MSAs. This pattern indicates that nonmetro primary care physicians preferred to locate in areas where distance made metro physician services less accessible to local residents.

The mean annual change in the overall primary care physician ratio was nearly constant, varying from 1.98 in 1975 to 1981 to 2.04 in 1981 to 1988 (Table 2). On average, communities thus gained about two primary care physicians per 100 000 residents per year during the late 1970s and 1980s. Although all urban and rural areas gained primary care physicians, the annual gains were greatest in metro counties and nonmetro urbanized remote counties. All other nonmetro counties added primary care physicians much more slowly.

The faster growth of the primary care physician supply in more urban areas caused urban–rural differences in the availability of practitioners to widen over time. The gap between metro and nonmetro areas expanded from 30 to 45 primary care physicians per 100 000 persons between 1975 and 1988 (Table 2). Differences within nonmetro areas also increased as nonmetro urbanized remote counties (and to a lesser extent, less urbanized remote counties) became more prominent centers of the primary care physician supply (Figure 1). The emergence of these centers indicates that nonmetro primary care physicians have become increasingly concentrated in counties with larger urban places, even though all areas gained practitioners.

Nonmetro counties gained primary care physicians more rapidly during the 1980s than the late 1970s (Table 2). In contrast, most metro counties (except large metro fringe counties) gained primary care physicians more slowly. The shift in growth rates indicates that nonmetro areas and the suburbs of large MSAs became more attractive to primary care physicians after 1981.

The urban–rural differences in the supply of primary care physicians were affected by the classification of internal medicine subspecialists as primary care physicians. However, subspecialists accounted for only a small part of the differences in 1988 when subspecialists could be distinguished from general internists. In that year 8% of the primary care physicians in metro areas and 3% of those in nonmetro areas were actually subspecialists.

In contrast, resident physicians accounted for a larger share of the urban–rural differences in the primary care physician supply. More than 20% of the primary care physicians in metro areas were in residency training in 1988, in comparison with only 4% of those in nonmetro areas. There was little change in these proportions over time. The differences in the availability of primary care physicians would be smaller if residents were excluded, but the important role of residents in staffing urban teaching hospitals would be ignored.

TABLE 1—County Urban–Rural Continuum Categories

Urban–Rural Continuum Category	Number of Counties	Percent of 1987 Resident Population
Total counties[a]	3070	100.0
Metro counties	710	76.8
1. Large metro counties		
a. Core counties containing primary central city of MSAs with 1980 populations of 1 000 000 or more	55	29.0
b. Fringe (suburban) counties of MSAs with 1980 populations of 1 000 000 or more	169	16.3
2. Medium metro counties in MSAs with 1980 populations of 250 000 to 999 999	289	22.4
3. Small metro counties in MSAs with 1980 populations under 250 000	197	9.1
Nonmetro Counties	2360	23.2
1. Urbanized counties with 20 000 or more urban residents in 1980		
a. Adjacent to an MSA[b]	137	4.4
b. Remote (not adjacent to an MSA)	150	3.7
2. Less urbanized counties with 2500 to 19 999 urban residents in 1980		
a. Adjacent to an MSA[b]	551	6.2
b. Remote (not adjacent to an MSA)	748	6.3
3. Rural counties with fewer than 2500 urban residents in 1980		
a. Adjacent to an MSA[b]	228	1.1
b. Remote (not adjacent to an MSA)	546	1.6

[a] Excluding Alaska.

[b] Counties were considered adjacent to an MSA when the county and MSA borders touched at more than one point and 2% or more of the county labor force commuted to the central county of the MSA.

Note: Metro = metropolitan; MSA = Metropolitan Statistical Area.

TABLE 2—Nonfederal Primary Care Physicians per 100 000 Resident Population by Urban–Rural Continuum Category, 1975–1988[a]

Urban–Rural Continuum Category	Primary Care Physician/ Population Ratio			Mean Annual Change in Primary Care Physician/ Population Ratio	
	1975	1981	1988	1975–1981	1981–1988
US Total	61.4	73.3	85.5	1.98	2.04
Metro	68.5	82.3	95.9	2.31	2.26
Large metro					
Core	86.6	101.9	116.0	2.56	2.34
Fringe	55.9	69.6	85.7	2.28	2.68
Medium metro	59.3	72.9	85.1	2.28	2.02
Small metro	52.0	65.1	76.2	2.18	1.86
Nonmetro	38.6	44.4	51.3	0.97	1.14
Urbanized					
Adjacent to MSA	42.1	47.9	54.8	0.98	1.14
Remote	46.3	57.8	69.3	1.91	1.92
Less urbanized

[a] Excluding Alaska.

Note: Metro = metropolitan; MSA = Metropolitan Statistical Area.

Specialist Physicians

During 1975 to 1988 the number of specialist physicians grew more rapidly than the number of primary care physi-

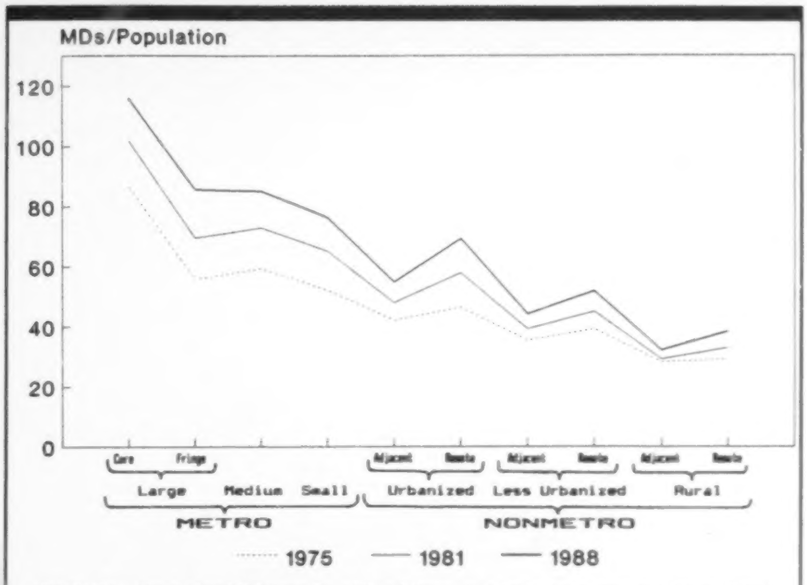

FIGURE 1—Nonfederal Primary Care Physicians per 100 000 persons by Urban–Rural Continuum Category, 1975–1988

cians, increasing by 4.2% per year from 147 200 to 242 900. As a result, the overall specialist physician population ratio rose from 68.4 to 100.0 (Table 3). The urban–rural distributions of specialists and primary care physicians were very similar (Figure 2). However, there were even greater differences between more urban and more rural areas in the supply of specialists. The specialist ratio was highest in the central areas of large MSAs and lowest in nonmetro rural counties. Within nonmetro areas, remote counties had more specialists than adjacent counties in the same urban population category.

The total supply of specialists grew more rapidly during the 1980s than the late 1970s (Table 3). All urban and rural areas gained specialists, but the gains were greater in more urban areas, repeating the pattern among primary care physicians. The increase in the specialist supply was particularly rapid in large MSAs, which gained more than three specialists per 100 000 persons per year. In contrast, the specialist supply grew only one tenth as rapidly in nonmetro rural counties.

TABLE 3—Nonfederal Specialist Physicians per 100 000 Resident Population by Urban–Rural Continuum Category, 1975–1988*

Note: Metro = metropolitan; MSA = Metropolitan Statistical Area.

Urban–rural differences in the availability of specialists widened over time due to the faster growth of the specialist ratio in more urban areas (Table 3). Between 1975 and 1988 the gap between metro and nonmetro areas expanded from 56 to 78 specialists per 100 000 persons. In nonmetro areas, urbanized remote counties also became more prominent centers of the specialist supply (Figure 2). Most nonmetro areas (except rural adjacent counties) gained specialists more slowly after 1981, but the central areas of large MSAs began gaining specialists even more rapidly.

The classification of internal medicine subspecialists as primary care physicians reduced urban–rural differences in the specialist ratio (see above). However, the inclusion of specialist residents increased the differences. During the late 1970s and 1980s about 17% of the specialists in metro areas were in residency training, in contrast to only 3% of those in nonmetro areas. The inclusion of residents is appropriate in view of their role in urban teaching hospitals.

Osteopaths

The number of osteopaths also grew rapidly between 1976 and 1987, increasing by 4.2% per year from 13 700 to 21 800. The osteopath/population ratio rose from 6.3 to 9.0 during the same period (Table 4). Urban–rural differences in the supply of osteopaths were small in comparison with the differences in the supply of allopaths. However, osteopaths were distributed across the urban–rural continuum in a distinct pattern, with the greatest supply concentrated in the most urban and most rural areas of the country (Figure 3).

The supply of osteopaths increased more rapidly after 1981 (Table 4). Some areas (nonmetro urbanized remote and less urbanized adjacent counties) actually lost osteopaths during the late 1970s. In contrast, all areas gained osteopaths after 1981, with the fastest growth occurring in the most urban and most rural areas.

Composition of the Physician Supply

The uneven distribution of primary care physicians, specialist physicians, and osteopaths across the urban–rural contin-

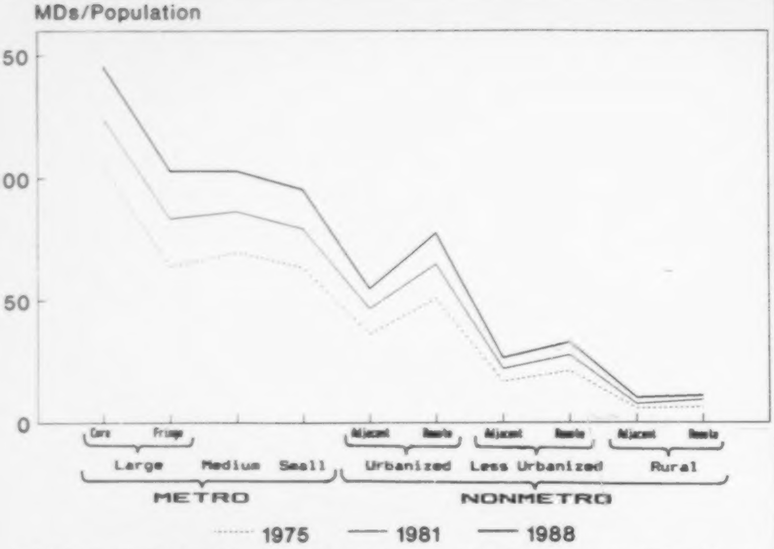

FIGURE 2—Nonfederal Specialist Physicians per 100 000 Persons by Urban–Rural Continuum Category, 1975–1988

uum produced major differences in the composition of the physician supply (Table 5). Primary care physicians represented a larger share of the physician supply in more rural areas, accounting for more than two thirds of the practitioners in nonmetro rural counties. In contrast, the proportion of specialist physicians was greater in more urban areas. The higher degree of physician specialization in more urban areas reflected the concentration of medical referral centers in cities and larger towns.

Osteopaths represented less than 5% of the physician supply during the late 1970s and 1980s (Table 5). However, they provided a disproportionate share of the physicians in more rural areas because they were relatively more willing to locate in nonmetro, less urbanized and rural counties than allopaths (Figures 1–3). By 1987 to 1988 more than 10% of the physicians in nonmetro rural counties were osteopaths. The role of osteopaths was even greater in eight states (Arizona, Florida, Michigan, Missouri, New Jersey, Ohio, Pennsylvania, and Texas) where licensing legislation was historically most favorable to the osteopathic profession.[17] In these states osteopaths accounted for 36% of the physicians in nonmetro rural counties.

The increasing specialization of the physician population had a direct impact on the composition of the physician supply. From 1975 to 1976 and 1987 to 1988 the proportion of primary care physicians declined, and the proportion of specialist physicians increased in every category of the urban–rural continuum (Table 5). The increase in the proportion of specialists was greatest in nonmetro counties.

Discussion

The evidence examined here indicates that the supply of nonfederal physicians increased in every part of the country. By the late 1980s all areas had more primary care and specialist physicians and osteopaths than in the mid-1970s. The rapid growth of the US physician supply was thus associated with the movement of more practitioners into predominantly rural areas, as well as urbanized rural and urban areas. However, the physician supply increased more rapidly in metro counties and nonmetro urbanized remote counties than in other nonmetro areas. As a result, urban–rural differences in the availability of physicians widened over time.

A major reason for the slow growth of the physician supply in predominantly rural areas may have been the limited number of places large enough to support physicians. Only 17% of the population of nonmetro rural counties lived in places with 1000 or more inhabitants in 1980.[18] The remainder of the population was dispersed in communities seemingly too small to support physicians, despite the spread of practitioners into more rural areas. However, this analysis was not designed to reveal the size of places within counties that actually gained physicians.

Osteopaths played a surprisingly important role in predominantly rural areas because they were relatively more likely to locate there than allopaths. As a result, osteopaths accounted for a disproportionate share of the physician supply in nonmetro rural counties, particularly in the eight states historically most hospitable to the profession. The factors that account for the greater willingness of osteopaths to locate in predominantly rural areas de-

serve further investigation in view of the reluctance of allopaths to practice in the same locations.

Despite the slow growth of the physician supply in predominantly rural areas, all nonmetro areas gained primary care physicians more rapidly during the 1980s than before. The faster growth may have been due to two different factors. First, increasing competition among physicians in metro areas may have encouraged more practitioners to select nonmetro locations. The slower growth of the primary care physician supply in most metro areas after 1981 supports this interpretation. Second, the number of general practice physicians decreased more slowly during the 1980s than the 1970s, elevating the net growth of the primary care physician supply.[19] The impact was greatest in nonmetro areas, where general practitioners represented a larger share of primary care physicians.

[b] Percents may not sum to 100.0% because of rounding.
Note: Metro = metropolitan; MSA = Metropolitan Statistical Area.

Specialist physicians in nonmetro areas were affected by different factors than primary care physicians because most nonmetro areas gained specialists more slowly after 1981. One possible factor may have been the limited number of places large enough to support specialists. By 1980 more than 36 million nonmetro residents lived outside places with 2500 or more persons in communities that the RAND studies showed rarely had specialists. However, more than 86% of this population lived in open country or places with fewer than 1000 persons that may never be able to support specialists.[18]

During the late 1970s and 1980s the physician supply in all areas also became more specialized. This trend was particularly dramatic in nonmetro rural counties, where the number of primary care physicians per specialist dropped from nearly five in 1975 to slightly more than three in 1988. The impact on the supply of medical services was unclear because specialists in rural areas may have spent much of their time providing primary care. The growth in the number of rural specialists also raised questions about the size of the case load needed to maintain physician expertise in specialized diagnostic and therapeutic procedures.[10]

Another important trend in nonmetro areas was the growing prominence of nonmetro urbanized remote counties as local centers of the physician supply. The rapid growth of the physician/population ratio and the higher proportion of specialists in these counties reflected the continuing development of secondary medical centers providing a variety of health services for rural areas some distance from major cities.[20] These centers were distinct from the tertiary medical centers in metro areas providing more specialized services for larger regions. The closing of hospitals in smaller rural communities and the greater competition from metro physicians in areas closer to cities may have contributed to the increasing concentration of physicians in rural secondary medical centers.

Nonmetro, less urbanized remote counties also became local centers of the primary care physician supply. These centers had fewer primary care physicians than nonmetro urbanized remote counties and did not have many specialist physicians. As a result, they appeared to be rural primary medical centers serving areas some distance from larger towns.

The most striking trend in metro areas was the continued rapid growth in the physician supply. It remains unclear whether this trend has produced a physician surplus because the demand for physician services depends on a complex variety of factors, including the costs of medical care, changes in health insurance coverage, advances in medical technology, the supply of midlevel health practitioners, and shifts in health care needs.

The even more rapid growth of the physician supply in large MSAs also deserved attention. By 1988 the suburbs of large MSAs had more primary care and specialist MDs than medium or small MSAs, reversing earlier patterns. The continued rapid growth was possible in part because physicians in large MSAs spent less time in patient care activities than those in other locations, restraining the actual growth in the supply of physician services.[22]

The variations in physician–population ratios described in this report do not necessarily reflect unequal access to physician services. Because many rural residents travel to urban areas to visit physicians, the average patient load per physician in rural areas is smaller than physician–population ratios suggest.[21] Rural physicians also work longer hours and see more patients than urban physicians, and this pattern reduces urban–rural differences in the supply of physician services.[22] Nevertheless, access to physician services outside densely populated urban areas still depends to a considerable extent on the location of physicians. In addition, rural communities have higher proportions of the poor and elderly than urban areas and may therefore require more physicians to meet local medical needs.[23]

Programs to provide more physician services in underserved areas need to take account of the fact that the most rural areas of the country remain unattractive to physicians. The present distribution of physicians in nonmetro areas suggests that it may be worth considering measures to encourage practitioners already located in rural primary and secondary medical centers to provide more care in surrounding areas. Some of the mechanisms that might be used to expand medical services into surrounding areas from these centers include mobile and satellite clinics, an increased role for midlevel health practitioners, and special transportation arrangements for nonemergency patients. ☐

Cognitive Impairment and Hospital Use

ABSTRACT

Background. An increasing number of older people are at higher risk of developing Alzheimer's Disease or another dementias. The resultant cognitive impairment has been well identified as one of the risk factors for nursing home placement but it has not been well studied as a risk for hospitalization.

Methods. To study the association between cognitive impairment and hospital use, this study examined data from a randomly selected cohort of community dwelling California elderly (California Senior Survey). The cohort was followed for one year (N = 940).

Results. Only about 17 percent of the study population was in the mildly or moderately/severe impaired category. Those participants with cognitive impairment were almost twice as likely as those without any impairment to be hospitalized and to be hospitalized for six days or more.

Conclusions. Although the cause of the cognitive impairment and hospitalization was not determined in this study, the data support the importance of cognitive impairment as a risk factor for hospital use even after controlling for age, ADL, IADL, and prior hospitalizations. The causes for this need to be further examined so the burden of such care can be reduced. (*Am J Public Health* 1991;81:1153–1157.)

Introduction

Cognitive status has been identified as one of the risk factors for nursing home placement[1] but it has not been well studied as a cause of hospitalization. Although several studies have looked at health services utilization due to Alzheimer's Disease or other dementias,[2–4] these studies have been mainly interested in estimating costs of care, particularly cost of nursing home care.[4] Further, they have relied largely on cross-sectional data sources and the number of individuals with cognitive impairment in some of these data sets has been small.

Few studies have looked at the hospitalization admission rate and length of stay in a random sample of community dwelling elderly based on their cognitive status. Huang and Hu[2] found that the elderly demented utilized an average of 4.81 days of short-term acute hospital care per person. This represented an additional utilization of short stay hospitals due to Alzheimer's Disease of 0.81–1.02 days per year based on the national hospital discharge survey data. Coughlin and Liu,[5] using data from the 1981–82 National Long-Term Care Channeling Demonstration Project and the Short Portable Mental Status Questionnaire (SPMSQ) to rate a person's cognitive status, found that the severely cognitively impaired spent a higher proportion of survival days in hospitals (.10) then mild/no cognitive impaired (.08) after six months of follow-up. More recently, Binder and Robins[6] found that community dwelling elderly were more likely to be hospitalized if they scored poorly on the Folstein Mini-Mental State Exam.

In response to the limited research on this topic, the purpose of the present study was to examine the relation between cognitive status and hospitalization in a randomly selected cohort of community dwelling Medicaid recipients. Additionally, the study examined the relation of cognitive status and length of hospital stays. The cohort was followed for one year.

Methods

Design

The data were drawn from the California Senior Survey (CSS), a random sample of community dwelling elderly MediCal (Medicaid) recipients from eight representative communities within California. The CSS respondents were randomly selected from files which contained the names, addresses, and other basic demographic data with all MediCal recipients. Only MediCal recipients 65 years of age and older were sampled. CSS respondents were interviewed face to face in their homes in 1982. Comparisons between the survey data and statewide data indicated that respondents were typical of California's MediCal elderly population.[7] More complete descriptions of the sampling methodology and sample characteristics have already been published.[7,8]

Hospital utilization data were obtained for one year following the inter-

view. The hospital utilization data came from MediCal paid claims and computer tapes which were merged with data obtained from Medicare intermediaries.[9] Combining these two sources provided data on number of days hospitalized for 92 percent of the original CSS sample (N = 1,037). To assure accuracy, the computer tapes were examined for any bills submitted for hospitalization during the follow-up year to either MediCal or Medicare intermediaries on behalf of CSS respondents. To overcome any problems that may have been caused by late billing, bills submitted up to two years following the interview were reviewed.

Besides those without hospital data, 15 other respondents were also dropped from the present study. Six lacked cognitive status data and nine had died within a few months of the survey and so their hospital data were necessarily censored. Analyses were run with and without these six respondents and they did not significantly affect the outcome. However, dropping these six respondents from the analyses was considered the more appropriate method. Although 25 other respondents also had died within a year of the baseline survey, they all had extensive hospital stays before their death and so it was possible to properly classify their hospital use for the present analyses.

No significant differences in terms of major sociodemographic and health status characteristics were noted between survey respondents with and without complete data. All respondents with complete hospital and cognitive status data were used for the study analyses (N = 940).

A structured measure of mental status was administered, the Short Portable Mental Status Questionnaire (SPMSQ). This instrument has high validity and test-retest reliability.[10] The widely used test is a 10-item questionnaire that is designed to measure several areas of intellectual domain including orientation, short- and long-term memory, general information, and problem solving. Pfeiffer[10] originally recommended adjustments for race and education. However, more recent versions of the SPMSQ only adjust for education.[11,12] Thus the present analysis chose to only adjust SPMSQ scores for education, although both race and education were entered as covariates in the multiple regression analysis.

Using Pfeiffer's recommendations, the SPMSQ scores used to categorize participants were: not impaired (0–2 errors), mildly impaired (3–4 errors), and moderately to severely impaired (over 4 errors).[10] The SPMSQ was administered in the elderly person's home by trained interviewers who also administered a comprehensive questionnaire composed of several previously described instruments.[13] Included in this battery were two commonly used functional status scales: the Activity of Daily Living (ADL) and Instrumental Activity of Daily Living (IADL) scale.[14,15]

Two dichotomous variables measuring hospital utilization were used: whether a respondent had been hospitalized within the year following the interview, and whether a respondent experienced a hospital stay of six or more days in the year following the interview. The figure of six days was selected because it was slightly higher than the average length of stay for all respondents (mean length of stay = 5.2 days).

Analysis

The present analyses used bivariate analyses (Chi-square) and odds ratios. A series of logistic regression models were used to examine the relation of the levels of cognitive status with the two indices of subsequent hospital utilization. Age, education, race, and prior hospitalizations during the year prior to the survey were controlled. The statistical program used was SAS and analyses were conducted on an IBM 3090 mainframe computer.

Study Population

Reflecting the diversity of California's ethnic population, the sample included a sizable portion of Blacks (17 percent), Hispanic (13 percent), and Asians (12 percent), although a majority (58 percent) were White. Seventy-two percent of the sample were females and over 60 percent of the sample lived alone. The age distribution of the sample was 42 percent (65–74 years of age), 44 percent (75–84 years old), and 14 percent (85 years old and over). The majority of participants were widowed (56 percent) with 23 percent being married, 6 percent single, and 15 percent separated or divorced. The educational level obtained by the participants was 33 percent finished high school and 19 percent had an education beyond high school, 6 percent had no formal education, and about 42 percent finished elementary school.

Results

Table 1 gives selected characteristics of the participants by level of cognitive impairment. Overall about 17 percent of the study population was either mildly or moderately to severely impaired. There was a higher prevalence of cognitive impairment in females than males. The prevalence of cognitive impairment increased significantly with age. Marital status was not related to cognitive impairment but cognitive impairment was more prevalent in those living with others than in those living alone. There were no race or ethnicity differences in the prevalence of cognitive impairment, but lack of education was associated with cognitive impairment.

3	85.8	7.8	6.5
4+	81.8	8.5	9.7

There was a significantly higher prevalence of cognitive impairment in those participants with two or more ADL dependencies. Similarly, an increased number of instrumental activities of daily living (IADL) dependencies was also significantly associated with cognitive impairment with money management having the strongest association (Table 2). The number of total chronic conditions was not significantly related to cognitive impairment (Table 3). Arthritis was negatively associated with cognitive impairment whereas stroke was positively related.

Odds ratios adjusted for age, education, race, and any hospitalizations during year prior to survey are shown in Table 4. Those participants with cognitive impairment were more likely to be hospitalized and to have increasing length of hospitalizations. Similarly, greater impairments on the ADL and IADL scales were associated with increased risk of hospitalization.

The number of dependencies on the ADL and IADL was collapsed into categories to facilitate analyses. Very few respondents had more than two ADL dependencies and so a single dependency on the ADL was considered a mild ADL impairment whereas being unable to perform two or more ADL functions was considered to be a moderate to severe ADL impairment. Cut points for the IADL were selected to maximize the relationship between IADL and hospital use. One to two IADL dependencies were judged to be a mild IADL impairment, three to four a moderate impairment, and five or more IADL dependencies were classified as a severe dependency. Any level of impairment on the SPMSQ was predictive of hospital use. Increased impairment on any of the scales was associated with increased risk of extended hospital stays. Further, Table 4 illustrates that those elderly with severe IADL impairments are especially at increased risk of longer hospitalizations. Mild impairment on the ADL was not generally associated with increased risk of hospital use.

Among the covariates, having been hospitalized during the year prior to the survey and being White were the only covariates related to subsequent hospital use. Previous hospitalization was the only covariate predictor of subsequent stays of six or more days (OR 2.73; CI = 1.96, 3.81).

To directly compare the SPMSQ with the ADL and IADL as predictors of hospitalization, additional logistic regression models were constructed. One set of models included both the SPMSQ and the ADL. Another set included the SPMSQ and the IADL (the ADL and IADL were too highly correlated to have included both of these functions in the same regression models). In these direct comparisons, the SPMSQ proved to be more predictive of future hospital use than the ADL but not as good as the IADL. Five or more dependencies on the IADL was an especially strong predictor of future hospital use even when controlling for moderate to severe impairments on the SPMSQ.

Discussion

The data are consistent with previous findings that cognitive impairment in community dwelling elderly is more common among females, older age groups, and those living with others.[16,17] The prevalence rates of cognitive impairment in studies of community elderly vary from a low of 1.6 percent (severe impairment) to a high of over 15 percent for the mildly impaired. The present study found an overall rate of 16.7 percent. The prevalence of cognitive impairment among the old old (85 years of age and older) was found to be higher (32.8 percent) than that previously reported (25 percent).[16] Two recent studies have also found higher than expected prevalence rates in the old old. Forty seven percent of those 85 years old

TABLE 4—Odds Ratios for Hospital Use by Level of Impairment

		Any Hospital Use		Hospitalized 6 Days or More	
	Percent With Impairment	Odds Ratio	(95% CI)	Odds Ratio	(95% CI)
ADLs					
Mild	26.7	1.30	(.92, 1.82)	1.42	(.97, 2.07)
Moderate/Severe	14.1	1.52	(.99, 2.33)	1.87	(1.19, 2.93)
IADLs					
Mild	45.0	1.52	(.87, 2.68)	2.95	(1.31, 6.64)
Moderate	26.8	2.04	(1.13, 3.69)	3.45	(1.50, 7.96)
Severe	16.8	3.48	(1.84, 6.55)	7.36	(3.12, 17.38)
SPMSQ					
Mild	9.3	1.85	(1.14, 2.98)	1.89	(1.14, 3.16)
Moderate/Severe	7.4	1.76	(1.03, 3.01)	2.10	(1.20, 3.68)

NOTE: Odds Ratios adjusted for age, education, race (White/non-White), and any hospitalizations during year prior to baseline survey.

These data categorize IADL dependencies as follows: 1-2 = mild; 3-4 = moderate; 7.5 = severe.

or older were found to have probable Alzheimer's disease in one study conducted in a geographically defined community in which 80.8% of the age-eligible residents were evaluated.[18] In another study of dementia in a retirement community, Pfeffer[19] found the prevalence rate of dementias to be 56.7 percent in those 85 years old and older. Although comparisons among various studies are difficult due to differing methods of case ascertainment, sampling methods and study populations, these data suggest that the public health impact of cognitive impairment in the elderly may be greater than previously described.

Our data do not support the concept of a racial or ethnic difference in cognitive impairment as implied in earlier suggestions for adjusted scoring of the SPMSQ.[10] The data did show a significant association between educational level and performance on mental status examinations. This association has been documented in other studies as well.[20] For example, Katzman[21] studied a probability sample of 5,055 community dwelling elderly in Shanghai. The Chinese Mini-Mental State (CMMS) was used to evaluate mental status. In comparison to those with formal education, this study found significantly lower scores on the mental status test as well as a different error pattern among the uneducated even after making adjustments for education. The reason for the association between educational level and suggested cognitive impairment has not yet been fully explained.[22]

Although the cause of the cognitive impairment and hospitalization were not determined in this study, the data indicate that cognitive impairment is a risk factor for hospital admissions and longer than average hospital stays even after controlling for age, ADL, IADL, and prior hospitalizations. The longer length of stay may be due to lack of appropriate posthospital placement or to complications of hospitalization.[23,24] Whatever the reasons for increased hospital use, the increasing prevalence of cognitively impaired elderly will result in an enormous financial burden for the patient, family, and government and has significant public health consequences.[25,26] □

Acknowledgments

The data used in this analysis come from the California Senior Survey, which was the comparison group for the California Multipurpose Senior Services Project (MSSP), a US Health Care Finance Administration (HCFA 115) research and demonstration project (Grant #11-P-07553).

This project was funded in part by the California Academic Geriatric Resource Program.

The German Health Care System: What Can We Learn from It?

As health costs continue to rise and many Americans find themselves without adequate health care coverage, attention has turned to other countries for answers. In recent years, Canada's government-run "single-payer" system has been the subject of intense debate. In the past year, though, interest has grown in the German "all-payer" health care system. Could it become a model for reforming health care in the United States? The May issue of *The Internist: Health Policy in Practice*, published by the American Society of Internal Medicine, examines what health care lessons can be learned from the German experience.

Uwe E. Reinhardt, PhD, the James Madison Professor of Political Economy at Princeton University, writes that if organized American medicine wishes to get ready for health care by the end of the century, it will need to study the "all-player" system of Western Europe in which "all players in a market area are bound by common fee schedules and all providers are subject to overall budget constraints." Dr. Reinhardt, who is a member of the Physician Payment Review Commission, adds that a move toward an all-payer system in the United States would require the development of a mechanism in which payers, including the federal and state government, could jointly negotiate binding fee schedules with the providers of health care.

German economist J. Matthias Graf von der Schulenburg observes that the annual increase of per capita health care spending in Germany was one of the lowest among industrialized nations between 1980 and 1987 (followed only by Japan, which more or less copied the German health care system). More than 1100 "statutory sickness funds"—self-sustaining, nonprofit institutions generally organized by geographic location, place of employment, or trade or profession—provide care for the German population. Although Germany saw a sudden increase in health care costs in the mid-1970s, Dr. Graf von der Schulenburg examines how costs came under control through negotiations at the different levels (federal, state, and local) of the health care system.

Although Germany's health care system has had a good record in restraining costs and prices, there have been trade-offs in terms of physician supply and demand, says Dale Rublee, PhD, a policy analyst with the American Medical Association. The growth in supply has become the medical profession's greatest long-range concern and Germany's most visible problem, he says. Germany has the most medical students per capita (next to Italy) and has seen rapid growth of medical specialists. The trade-off with an oversupply of physicians has been an overall decrease in physician earnings in the past few years in Germany.

Robert B. Doherty writes in *Capital Currents* that recent studies reporting that a quarter of all health care spending goes to "administrative waste" is overstated and that the data, especially concerning overhead, need to be closely examined. Doherty, ASIM's vice president of governmental affairs and public policy, adds that one of the reasons overhead costs may seem to be higher in the United States than in other countries is that more dollars are invested in quality assurance (such as peer review organizations or continuing medical education requirements).

Cause-Specific Mortality in a Population-Based Study of Diabetes

ABSTRACT

Background. Mortality from vascular diseases has been reported to be high in diabetic persons.

Methods. To evaluate mortality from these and other specific causes, we examined cause-specific age-sex standardized mortality ratios in a geographically defined population of younger onset (diagnosed before age 30 and taking insulin, n = 1200) and older onset (diagnosed after age 30, n = 1772) diabetic persons followed for 8.5 years. Cause of death was determined from death certificates.

Results. In younger onset persons, age-sex standardized mortality ratios were significantly high ($P < .05$) for all causes of death (7.5) as well as for diabetes (191), all heart disease (9.1), ischemic heart disease (10.1), other heart disease (6.3), nephritis and nephrosis (41.2), accidents (2.9), and all other causes (3.2). In older onset persons, age-sex standardized mortality ratios were significantly high for all causes of death (2.0) as well as for diabetes (16.8), all heart disease (2.3), ischemic heart disease (2.3), other heart disease (2.1), stroke (2.0), and pneumonia and influenza (1.7).

Conclusions. Diabetic persons experience very high mortality, especially from vascular diseases, compared to the general population. (*Am J Public Health.* 1991;81:1158–1162)

Scot E. Moss, MA, Ronald Klein, MD, MPH, and Barbara E. K. Klein, MD, MPH

Introduction

Diabetic persons have been shown to be at greater risk of mortality from cardiovascular disease,[1-18] stroke,[1,2,5,9,11] and renal disease[14,19] compared to nondiabetic persons. Risk estimates for cancer have been variable.[1,3,11,14,15,20] Many of these earlier results are based on clinic populations, include only people with type I or type II diabetes, include males only, or are based on small numbers of cases. Thus, the results of many of these studies may not be applicable to a wider diabetic population.

In the current investigation we examine data from a population-based study, the Wisconsin Epidemiologic Study of Diabetic Retinopathy. Cause-specific mortality from this sample of diabetic persons is compared to the general population.

Methods

The study population has been described in detail in previous reports.[21-23] The study area is composed of 11 counties in southern Wisconsin (1980 population of 839 324). Diabetic persons were identified by a review of the records of 452 of the 457 physicians providing primary care to diabetic persons in the year beginning July 1, 1979. Chart reviews were done on 9841 patients. Of these, 558 were excluded because they were confined to nursing homes, had died prior to July 1, 1979, had incorrect diagnostic codes, had moved, or had gestational diabetes.

A two-part sample of 2990 of the remaining 9283 patients was selected on July 1, 1980, for examination. The first part consisted of all persons diagnosed before age 30 and taking insulin, referred to as younger onset (n = 1210). The second part consisted of a probability sample of persons diagnosed as having diabetes after age 30 confirmed by a random or postprandial serum glucose of at least 11.1 mmol/L or a fasting serum glucose of at least 7.8 mmol/L on at least two occasions, referred to as older onset (n = 1780). The specifics of the sampling strategy and exact proportions appear in an earlier publication, but approximate proportions were 25% for eligible persons with 0 to 4 or 5 to 14 years duration and 100% for persons with 15 or more years of diabetes.[23] Of the older onset group, 824 were taking insulin and 956 were not. Because it was not possible to examine the entire population, these sample sizes were chosen to ensure that an adequate number of cases of diabetic retinopathy would be found to evaluate risk factors for this complication.

Of the original sample, 18 (10 younger onset and 8 older onset) had died or were lost prior to July 1, 1980. These persons were excluded from further analysis. The remaining persons were contacted annually by telephone to determine vital status. In addition, relatives, designated contact persons, and physicians were contacted, and newspaper obituaries were reviewed daily. An annual request was made to the Wisconsin Center for Health Statistics, Section of Vital Statistics, for death certificate information. Wisconsin death rec-

ords through 1988 have been searched. Finally, information on persons who moved out of Wisconsin and were suspected of being deceased and persons lost to follow-up was submitted to the National Death Index at the National Center for Health Statistics for matching against national death data through 1987.

The study period was from July 1, 1980, through December 31, 1988. Only deaths that had been confirmed by a death certificate were included in the analysis. Persons who were thought to be deceased but for whom a death certificate could not be located were considered to be alive as of the last contact date they were known to be alive. An analysis was undertaken at this time because nearly half of the older onset group had died, affording adequate deaths to examine a number of underlying causes. While the number of deaths in the younger onset group is considerably smaller and should probably be regarded as preliminary, it is still large enough to investigate the major causes of death.

All medical conditions on the Wisconsin death certificate were coded by trained nosologists in the Wisconsin Division of Health using the International Classification of Diseases, Ninth Revision (ICD-9). The underlying cause of death was selected by the Automated Classification of Medical Entities computer program.[24,25] Out-of-state certificates were coded and processed in the same manner. The cause-specific mortality analysis of the present investigation was based on the underlying cause of death.

Standardized mortality ratios (SMR) were used to compare the mortality experience of the two diabetes groups with that of the general Wisconsin population.[26] The Wisconsin rather than the US population was used as the standard because it is closer in racial and ethnic composition to the diabetic population, which is predominately non-Hispanic White. Age-, sex-, and cause-specific deaths and age- and sex-specific population estimates for the standard population were obtained from published tables.[27,28]

Results

TABLE 1—Vital Status of Younger and Older Onset Diabetic Persons, Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1988

	Younger Onset		Older Onset	
Status	n	%	n	%
Confirmed dead	145	12.1	859	48.5
Suspected dead[a]	5	0.4	17	1.0
Alive at last contact	1039	86.6	883	49.8
Lost to follow-up[b]	11	0.9	13	0.7
Total	1200	100.0	1772	100.0

[a] Treated as alive as of last contact at which known to be living.
[b] No contact for more than 2 years.

Males comprised 52.2% of the younger onset group and 45% of the older onset group. Mean age at diagnosis and standard deviation (SD) in the younger onset group was 14.6 ± 7.6 years. In the older onset group, mean age ± SD at diagnosis was 55.5 ± 12.6 years. Mean age ± SD at the start of the study was 28.4 ± 13.3 and 66.7 ± 11.5 years in the younger and older onset groups, respectively.

The vital status of the younger and older onset groups is presented in Table 1. There have been 145 (12.1%) and 859 (48.5%) confirmed deaths in the younger and older onset groups, respectively. Only 5 (0.4%) younger onset and 17 (1%) older onset deaths have not been confirmed. In addition, only 11 (0.9%) younger onset and 13 (0.7%) older onset persons have been lost to follow-up.

Table 2 presents the distribution of underlying cause of death among diabetic persons for the 12 most common causes of death in Wisconsin. In the younger onset group, diabetes was the leading underlying cause of death, accounting for 44.1% of all deaths. This was followed by heart disease (30.3%) and accidents (6.2%). In the older onset group, heart disease (48.8%) was the leading underlying cause of death, followed by diabetes (15.3%), malignant neoplasms (9.9%), and cerebrovascular disease (9.5%).

Standardized mortality ratios (SMR) by cause of death in the younger onset group are shown in Table 3. Mortality from all causes was 7.5 times more than expected from the general Wisconsin population and was more in excess in females (8.9) than in males (6.8). Among specific underlying causes of death, mortality from diabetes was 191 times greater than that expected. The SMR for heart disease was 9.1, with the excess being greater in females (10.3) than in males (8.7). The difference was more pronounced for ischemic heart disease (SMR of 13.5 in females, 9.1 in males). However, excess mortality for other heart disease was greater in males (7.3) than in females (4.5). There was also a sex difference with respect to mortality from accidents. The SMR for females (5.9) was significantly different from unity while in males it was not (2.0). The only other statistically significant excess mortality was due to nephritis and nephrosis (41.2). There were too few deaths from this cause to separate the sexes. Other SMRs, while substantially greater than unity, were not statistically significant, possibly due to a lack of power because of the small numbers of observed and expected deaths (Table 3).

Table 4 displays SMRs by cause of death in the older onset group. Mortality from all causes was twice the expected, and the excess was slightly greater in females (2.2) than males (1.9). As in the younger onset group, the greatest excess was due to diabetes (16.8). Mortality from heart disease was 2.3 times the expected and affected the sexes equally. Excess mortality due to ischemic heart disease was slightly higher in males while that due to other heart disease was higher in females. Cerebrovascular disease mortality was twice the expected. The only other statistically significant excess mortality was due to pneumonia and influenza (1.7).

Discussion

Many of the studies of cause-specific mortality among diabetic persons compared to nondiabetic persons are of clinic populations,[2,5,14,20] industrial or worker groups,[1,4,9,10,17] or other groups that are not population-based.[11] Clinic populations of diabetic persons may be biased in that they may be more likely to be suffering from complications of diabetes and have a poorer survival experience. Indeed, we have shown that in terms of all-cause mortality, diabetic persons with ocular diseases are at a disadvantage compared to those without.[29] On the other hand, studies based on worker groups may experience bias due to the "healthy worker" effect. Thus, population-based studies or studies based on a representative sample of a population offer the best opportunities for assessing the effect of diabetes on mor-

Note. Sex-specific SMRs are not given where there are fewer than five total deaths.

tality. The present population-based study is notable for its substantial population of both younger and older onset diabetic persons of both sexes.

The population-based studies carried out in the United States have all found an excess mortality from cardiovascular disease.[3,6,7,12,16,18] These studies found SMR and relative risks (RR) in the range of 1.7 to 4.9. Although SMR and RR are not strictly comparable, they may give similar results in practice. The studies cited include both insulin- and noninsulin-dependent diabetic persons and thus are probably most comparable with our older onset group. In our older onset group we found an SMR of 2.3 for cardiovascular disease. This agrees remarkably well with the other population-based studies.[3,6,7,12,16,18] In addition, several of these studies note a differential effect of sex on cardiovascular disease

TABLE 4—Observed (O) and Expected (E) Deaths, Age- and Sex-standardized Mortality Ratios (SMR), and 95% Confidence Intervals (CI) by Cause of Death and Sex in Older Onset Diabetic Persons, Wisconsin Epidemiologic Study of Diabetic Retinopathy, 1980–1986

	Male			Female			Total

All other causes	31/21.6	1.4	1.0–2.0	28/24.4	1.1	0.8–1.7	59/46.0	1.3	1.0–1.7
Total	409/221.1	1.9	1.7–2.0	450/206.0	2.2	2.0–2.4	859/429.1	2.0	1.9–2.1

Note: Sex-specific SMRs are not given where there are fewer than five total deaths.

mortality in diabetic persons wherein females are at greater risk relative to nondiabetic persons than males.[6,7,12] However, this finding is not universal.[16,18] We also find no sex differential for either all heart disease or ischemic heart disease in the older onset group, but we do find one in the younger onset group, especially with respect to ischemic heart disease. However, in the Framingham study a trend is noted where the sex differential in cardiovascular disease incidence diminishes with advancing age.[6] If this effect carried over to mortality, it could explain our result.

Several studies have also investigated cerebrovascular disease mortality among diabetic persons.[1,2,5,9,11] Although none of these studies are population based, most of them found varying degrees of excess cerebrovascular disease mortality among diabetic persons. We found a significant twofold excess mortality from cerebrovascular disease in our older onset group. In the younger onset group there is a fourfold excess cerebrovascular disease mortality, but it does not reach statistical significance. However, the SMR is based on only three deaths.

Cancer was investigated in several studies with varying results.[1,3,11,14,15,20] In some studies cancer mortality did not differ from expected,[1,3,11,14] in one it was higher than expected,[15] and in one it was lower than expected in males only.[20] In two of these the results are based on small numbers of deaths,[1,14] and only two are population based.[3,15] We did not find that cancer mortality differed from the expected in either the younger or older onset groups.

Renal disease mortality has been found to be high in younger diabetic persons,[14] but the effect decreases sharply with age.[19] We also found excess mortality due to renal disease in the younger onset group. Mortality due to renal disease in the older onset group, while nearly double that expected, was not statistically significant. However, the real impact of renal disease on mortality in our population may be underestimated because some cases may also be included under diabetes as ICD-9 code 250.4, Diabetes with renal manifestations. If we add these to the other cases of renal disease, then the SMR for nephritis and nephrosis in the younger onset group is 72.1 (95% CI = 28.9–148.5), and in the older onset group it is 2.6 (95% CI = 1.3–4.7).

Two studies reporting on mortality from accidents and suicides combined, showed lower than expected mortality in males and higher than expected mortality in females.[2,14] In the younger onset group, we found higher than expected mortality from accidents in both males and females. In the older onset group, males had lower than expected and females had higher than expected mortality from accidents. In both groups only the result for females was statistically significant. Also, we found higher than expected suicide mortality in the younger onset group and lower than expected in the older onset group, but neither is statistically significant.

The only other significant result is higher than expected mortality due to pneumonia and influenza in the older onset group. We have not found this specific cause of death reported elsewhere. However, because we have a large number of deaths, especially in the older onset group, we are able to examine more specific causes of death than other population-based studies with smaller samples of diabetic persons. ☐

Acknowledgments

This research was supported by grant EY-03083 from the National Eye Institute (R. Klein). We are grateful to Fred Krantz, Wisconsin Center for Health Statistics, for providing death certificate information on Wisconsin residents, to Betty Sullivan and Peggy Peterson, Wisconsin Center for Health Statistics, for coding death certificates of out-of-state residents, to Stacy Meuer and Ane Weber for data processing, to Kathryn Linton and David DeMets for their helpful comments, and to Colleen Comeau and Luann Dohm for assistance with the manuscript.

Hypertension Management in Health Care for the Homeless Clinics: Results from a Survey

Kraig Kinchen, BS, and James D. Wright, PhD

ABSTRACT

Background. With the exception of alcohol abuse, hypertension is the most common chronic physical health problem encountered among homeless persons. The material conditions of homelessness greatly complicate the management of this disorder. Some of the complications and their solutions are discussed here, based on the experiences of health clinics for the homeless in large US cities.

Methods. In 1988, the Stewart B. McKinney Homeless Assistance Act established health care clinics for homeless persons in 108 cities. We surveyed medical directors in these clinics, asking about the management of hypertension in this difficult-to-treat population; 65 responded.

Results. Comparisons between our survey data and those obtained in two recent surveys of clinicians in "normal" clinical practice provide interesting lessons in how medical practice is adapted to respond to the unique needs and problems of the urban homeless. Although therapeutic goals are similar, the means chosen to achieve them often are not.

Conclusions. The treatment of homeless hypertensives illustrates the problems inherent in strict biomedical models of disease and its alleviation. Preferred treatments, course of disease, and success of intervention are powerfully affected by social factors. (*Am J Public Health*. 1991;81:1163–1165)

Introduction

With the exception of alcohol abuse, hypertension is the most common chronic physical health problem encountered among homeless persons, afflicting between 14% and 25% of this population.[1–4] The management of hypertension in the homeless is complicated by material and existential conditions. Proper dietary practice is exceedingly difficult to maintain,[5] rates of alcohol abuse exceed 50%,[4] storage and administration of medicines are difficult, and the cost of medication can be prohibitive. Compliance and maintenance of contact with homeless hypertensives are also difficult, and the asymptomatic stages of the disease produce little or no motivation to seek or maintain treatment.

In 1984, the Robert Wood Johnson Foundation, sensing the widespread unmet medical needs of the nation's homeless, funded health care for the homeless (HCH) clinics in 19 cities. In 1988, the McKinney Homeless Assistance Act extended the system to an additional 89 cities. We surveyed these 108 HCH clinics to learn how medical practice is adapted to the unique needs of homeless hypertensives, using a questionnaire loosely modeled on two recent surveys of hypertension management in "normal" clinical practice.[6,7] One of the clinics served only children and was dropped from the sampling frame; responses were obtained from 65 (60.7%) of the remaining 107 clinics.

Results

Initiation of Therapy

The Joint National Committee for the Detection, Education, and Treatment of High Blood Pressure (JNC)[8] recommends initiation of drug therapy when diastolic blood pressure (DBP) exceeds 94 mm Hg or at somewhat lower pressures if other risk factors are present; nondrug therapies are recommended for DBP between 90 and 94 mm Hg. HCH physicians largely adhere to the JNC recommendations. For an otherwise asymptomatic 45-year-old homeless white male, nondrug therapy would be initiated at an average DBP of 90.5 mm HG or at an average systolic blood pressure (SBP) of 151 mm Hg. Likewise, drug therapy would usually be initiated at a DBP of 97 mm Hg and at an SBP of 161 mm Hg. In both respects, HCH physicians differ little from clinicians in Maryland and New York City. Therapeutic goals are also very similar in both settings, with DBP <90 mm Hg as the target for the overwhelming majority.

The importance of factors other than blood pressure in deciding to initiate therapy was rated on a 1 (not important at all) to 4 (very important) scale. The most important other factor is target organ damage (mean rating [MR] = 3.88). (In a sample of homeless hypertensives being treated in the New Orleans HCH clinic, 20% had concurrent heart problems, compared to 2% of the normotensives.[2]) The co-occurrence of diabetes mellitus (MR = 3.79), elevated blood cholesterol (MR = 3.39), and being a smoker (MR = 3.32) were also rated as important factors in the decision to initiate therapy.

TABLE 1—Percentage of Physicians Performing Various Laboratory Tests in the Initial Diagnostic Evaluation of a Recently Diagnosed Hypertensive Man

Laboratory Test	New York City	Maryland	HCH
Aldosterone	5	NR	0
Blood Urea Nitro	95	NR	85
Chest radiograph	100	70	34
CBC	100	67	66
Electrocardiogram	100	89	63
Intravenous pyel	19	11	5
Plasma renin	0	7	2
Serum cholesterol	95	NR	89
Serum creatinine	90	84	92
Serum potassium	100	82	86
Triglycerides	67	NR	55
Uric acid	90	NR	60
Urine culture	24	NR	0
Urinalysis	100	NR	94

Note. HCH = Health Care for the Homeless; NR = not reported.
Sources: New York City[7]; Maryland[8]; HCH, authors' survey.

Laboratory Protocols

Initiation of therapy usually implies a detailed laboratory workup to assess other risk factors and to establish baseline values.[8] Table 1 compares laboratory protocols of HCH physicians with those in Maryland and New York. Urinalysis, serum creatinine, serum cholesterol, and serum potassium tests are the most common laboratory tests ordered in all three settings but all tests except serum creatinine and potassium tests are less likely to be ordered in HCH settings, apparently because most HCH clinics do not have their own laboratories. One respondent noted, "Obtaining initial lab tests in our program requires sending a homeless hypertensive patient to our central health center." Resistance to treatment and absence of a fee source often preclude sending homeless hypertensives off-site for laboratory work. Routine tests are seen as needless complications or unaffordable luxuries.

Nondrug Therapies

We asked HCH physicians how frequently they recommended various nondrug therapies; the Maryland survey asked a somewhat different question that, nonetheless, provides interesting comparisons. In the Maryland study, the most important nondrug therapies, in descending order of importance, were sodium reduction, weight reduction, smoking reduction, increased exercise, and alcohol reduction. Among HCH physicians, alcohol reduction is by far the most important, followed at some distance by sodium reduction, weight reduction, and fat restriction. Alcohol abuse is strongly associated with blood pressure levels in all patient populations[9,10]; the greater importance accorded alcohol reduction by HCH physicians doubtlessly reflects the exceptional rate of alcohol abuse, especially among homeless men.

Dietary control of hypertension is obviously problematic in any population that depends on soup kitchens and bread lines for its sustenance. As one homeless hypertensive in New Orleans put it, "You gotta eat what they put on the plate." Since the prospects of dietary control for homeless patients are dim, they are accorded less importance in HCH clinics than elsewhere. The same can be said of other nondrug therapies often employed in conventional settings. Relaxation therapy is obviously pointless when maintaining the most basic necessities of life is a daily struggle. Smoking reduction may be equally pointless when cigarettes are the only remaining pleasure in life. The barriers to managing homeless hypertensives with nondrug therapies usually mean that antihypertensive drugs are the treatment of first *and* last resort.

Drug Therapies

Most HCH clinicians (45%) consider diuretics the treatment of choice, followed by calcium channel blockers (26%), beta blockers (12%), acetylcholinesterase inhibitors (11%), and "all others" (3%). Cost and availability of medications are more important factors in treating homeless hypertensives because the regimen is often life-long and therefore expensive. Nearly four fifths of HCH physicians cited cost as an important factor. Said one, "Newer and often more effective medicines can't be initiated because the homeless and the agencies that care for them can't afford them. The older medicines, with frequent dosing intervals and side effects, are the only ones we have available." Cost is not usually cited as a critical factor in HCH clinics that provide free medication.

Treatment and Compliance

A recent study of homeless hypertensives in New Orleans found that 59% had their blood pressures under control at least once in the course of treatment and 40% were in control at the last visit[2]; 60% of the domiciled hypertensives in a San Francisco study had normal blood pressure readings at their last visit.[11] Thus, effective treatment of homeless hypertensives is difficult but not entirely hopeless.[1,12,13]

One difficulty in treating the homeless is noncompliance, but this is also a problem for domiciled hypertensives.[14,15] Still, 91% of HCH physicians felt that compliance was more difficult for the homeless. Perceived barriers to compliance are summarized in Table 2. Alcohol abuse and availability of medication require no further comment. In domiciled populations, "The amount of social support a patient receives is strongly correlated with adherence to treatment" (p 355)[14]; among the homeless, estranged and disrupted social networks are common.[16] Further, approximately one homeless person in three is psychiatrically impaired.[17] Homeless patients frequently have trouble keeping appointments because they lack the routines of family and work, and many have no sense at all of day, month, or even year.

Strategies

How do HCH clinicians cope with the many difficulties summarized above? As one noted, with "Perseverance, patience, and creativity." To reduce confusion about medication, many HCH physicians prescribe once-daily dosages; to maintain contact, they schedule more frequent appointments and write prescriptions for shorter periods. Most HCH clinics also employ outreach workers to monitor clients in the streets. At least one HCH clinic has a "no-wait" drop-in station to provide immediate blood pressure readings. Many HCH facilities provide in-clinic medication storage. When possible, medication is dispensed in weather-resistant packages. At least three HCH clinics have experimented with clonidine transdermal patches, which eliminate the storage and daily-dosage problems altogether.[12,13]

TABLE 2—Relative Importance of Nine Factors in Impeding Compliance among Homeless Hypertensives: HCH Physician Assessments

Factor	Rated Importance[a]
Alcohol abuse	3.79
Unavailability of medication	3.76
Lack of social support network	3.42
Psychiatric impairment	3.40
Difficulty keeping appointments	3.34
Resistance to life-style changes	3.24
No place to store medication	3.10
Inadequate understanding of the effects of hypertension	3.08
Side effects of medication	2.63

Note. HCH = Health Care for the Homeless

[a] On a 1–4 scale where 1 = not important and 4 = very important.

One powerful incentive for hypertensives to maintain contact is that other needs can also be addressed at the HCH clinic. Most clinics have social workers, case managers, substance abuse counselors, and other service workers as well as medical personnel. Many of these clinics have evolved essentially into "one-stop" social service centers. Professional nutritionists can help with dietary management; 23% of the HCH clinics had a nutritionist on staff and an additional one third had access to nutritionists via referral.

The biggest barrier to treatment of homeless hypertensives, of course, is that their overall physical and mental well-being is threatened by much more pressing concerns than elevated blood pressure. Given their lack of food, clothing, shelter, and money, there is little concern among the homeless with preventive health measures or health maintenance.

Comment

Homelessness is a social condition with profound consequences for physical well-being, including the effective management of chronic physical disorders such as hypertension. The treatment of homeless hypertensives illustrates the folly inherent in strict biomedical models of disease and its alleviation. The range of treatments available, the course of the disorder, and the success of intervention are all powerfully affected by social factors.

It is an unfortunate commentary that we invest as much in providing health services for the homeless as we do in eradicating the basic causes of homelessness. People cannot be socially, mentally, or physically healthy without first having a stable and secure place to live. Health care clinics help homeless people lead more comfortable, less degrading lives, but they do little to reduce the number of homeless persons. Health care for the homeless, however creative, sensitive, and professionally motivated, cannot and does not address the more basic problems. The ultimate folly would be to become so proficient in dealing with the health consequences of homelessness that we lose sight of the fundamental problem of homelessness. ☐

Epidemiologic Studies Utilizing Surveys: Accounting for the Sampling Design

Edward L. Korn, PhD, and Barry I. Graubard, MA

ABSTRACT

Background. Since large-scale health surveys usually have complicated sampling schemes, there is often a question as to whether the sampling design must be considered in the analysis of the data. A recent disagreement concerning the analysis of a body iron stores-cancer association found in the first National Health and Nutrition Examination Survey and its follow-up is used to highlight the issues.

Methods. We explain and illustrate the importance of two aspects of the sampling design: clustering and weighting of observations. The body iron stores-cancer data are reanalyzed by utilizing or ignoring various aspects of the sampling design. Simple formulas are given to describe how using the sampling design of a survey in the analysis will affect the conclusions of that analysis.

Results. The different analyses of the body iron stores-cancer data lead to very different conclusions. Application of the simple formulas suggests that utilization of the sample clustering in the analysis is appropriate, but that a standard utilization of the sample weights leads to an uninformative analysis. The recommended analysis incorporates the sampling weights in a nonstandard way and the sample clustering in the standard way.

Conclusions. Which particular aspects of the sampling design to use in the analysis of complex survey data and how to use them depend on certain features of the design. We give some guidelines for when to use the sample clustering and sample weights in the analysis. (*Am J Public Health.* 1991;81:1166–1173)

Introduction

Many biomedical questions involving human populations cannot be answered by experimentation. We cannot ethically randomize patients to certain risk factors, e.g., exposure to asbestos. For factors we can manipulate, we may be unwilling to wait the required number of years or to follow the large number of individuals necessary for a meaningful analysis. Epidemiologic studies offer an alternative to randomized experiments that can avoid the major ethical problems and sometimes allow reduced sample sizes and earlier completion times.

Depending on the risk factors and outcomes, epidemiologic studies may still require large sample sizes. Large multipurpose health surveys can be a readily available source of data. An advantage of this type of data is that many risk factors can be examined. For example, consider the National and Hispanic Health and Nutrition Examination Surveys—NHANES I, II, III and HHANES—conducted in 1971–1975, 1976–1980, 1988–1994, and 1982–1984, respectively. Table 1 gives some examples of cross-sectional associations that have been studied using these surveys. Also, because these surveys were done at different times, one can examine cross-sectionally changes over time in various measured quantities (Table 1). In 1982–1984, a follow-up survey was conducted of NHANES I sampled individuals aged 25 to 74 years. This follow-up survey allows true longitudinal studies to be conducted (see Table 1 for examples). With diminishing financial resources, we believe that these types of surveys will be used increasingly to investigate biomedical and public health hypotheses.

A question that usually arises in the analysis of such survey data is whether the complex sampling design, which involves the clustering and weighting of observations, needs to be accounted for, or if it can be ignored by treating the sampled data as the population of interest. In some[5,7–12,15–20,22,23,25–36] of the above mentioned studies the sampling design was used in the analysis, while in others[1–4,6,13,14,21,24,37–53] it was not. The recent analysis by Stevens et al.[41] that ignored the sampling design in the analysis crystallizes the issue. Among other findings, Stevens et al.[41] found statistically significant differences in the mean total iron-binding capacity and mean transferrin saturation between men who developed cancer and men who did not, controlling for age and smoking status. Yip and Williamson[54] criticized this study because the sampling design was not used, and suggested that if it had been incorporated in the analysis, "it is doubtful that [these differences] would have remained 'statistically significant'." Stevens and colleagues replied, "It is important to take into account the probability sampling method used by NHANES when one is attempting to estimate the level of a variable in the US population at large. To test for differences between case patients and controls within the NHANES cohort, however, the methods we used are appropriate."[55] What is the correct approach to the analyses of these types of studies?

TABLE 1—Examples of Studies Using Data from the National Health and Nutrition Examination Surveys

Outcome	References	Risk Factors/Subgroups
Cross-sectional associations		
Blood pressure	1–8	Nutrient intake; alcohol intake; blood lead levels; anthropometric measurements; race, sex, and age
Body weight	9–10	Smoking; alcohol
Anxiety	11	Aspects of diet
Periodontal disease	12	
Tooth decay	13	
General health	14	
Serum cholesterol	15	
Dietary supplements	16	
Blood iron levels	17	
Dietary pattern	18	
Constipation	19	
Glucose tolerance	20	Oral contraceptives; job characteristics
Cardiovascular disease	21–22	
Blood iron	23–24	Race, sex, and age
Blood lead	25	
Serum vitamin A	26	
Serum retinol	27	
Serum α-tocopherol	28	
Dietary intake	29	
Low birth weight	30	
Changes over time measured cross-sectionally		
Blood pressure	31	
Blood lead levels	32	
Anthropometric measurements	33	
Oral contraceptive use	34	
Incidence of childhood asthma	35 36	
Longitudinal studies		
Incidence of cancer	37–44	Alcohol intake; serum cholesterol; dietary fat; anthropometric measurements; blood iron; bowel function; physical activity; depression
Cardiovascular disease mortality	45	Cardiac size
Mortality from injuries	46	Alcohol consumption
Mortality (all causes)	47–50	Diabetes; race; antihypertensive drugs; self-rated health status
Depression	51	Physical activity
Hip fracture	52	Anthropometric measurements
Psychological well-being	53	Age

This article offers a brief tutorial about the sampling design and analysis of large household surveys. We examine whether the sampling design should be used when analyzing cross-sectional or longitudinal data derived from such surveys. We do not consider case-control studies, for which it is generally agreed that the sampling design must be considered in the analysis.[56–58] We consider conditions under which the sampling design can be safely ignored and the inefficiency resulting from utilizing the sampling design when it was unnecessary. The NHANES I and its follow-up are used as illustrations throughout, with special emphasis on the body iron stores-cancer association found by Stevens et al.[41]

Design of Complex Surveys: Cluster Sampling and Sample Weights

In this section the NHANES I design is used to describe the complex sampling design of household surveys. We stress the points of the design relevant to the issues discussed in this paper; other sources[59–61] provide further details. Although simple random samples are the easiest to analyze, they are impractical for large-scale national surveys for two reasons. First, no national registry of names to be sampled may exist. Second, even if a simple random sample of names could be obtained, it would be impractical to travel to, say, 20 000 locations scattered throughout the United States to interview the sampled individuals. Multistage survey designs, on the other hand, enable sampling frames to be developed for a relatively small number of areas and limit the number of locations to which interviewers must travel. For example, in the first stage of NHANES I sampling, the mainland United States was divided into approximately 1900 geographic areas or primary sampling units (PSUs), each one consisting of a standard metropolitan statistical area or, at most, three contiguous counties. These PSUs were grouped into 40 strata from each of which one or two PSUs were sampled; some very large PSUs were sampled with certainty. In each of these sampled PSUs, successive stages of sampling involved census enumeration districts (approximately 300 households), segments (approximately 8 contiguous housing units), and sampled individuals.

At first glance accounting for this type of multistage clustering in the analysis of survey data seems a formidable task. Fortunately, approximate analytic methods have been developed that require only the knowledge of the stratum and PSU of each individual.[62] In practice, computer data files from large surveys contain this information so that it can be readily accessed by statistical computer packages. For NHANES I, the design can be approximated[60] for the statistical analysis as a selection of 70 PSUs, two from each of 35 strata.

For complex surveys, each sampled individual with data has a sample weight associated with his or her data. The sample weight is the number of individuals in the target population that the sampled individual represents. The sample weight may be derived as the product of three components. The first comes from the fact that surveys frequently over-sample certain groups in the population (base weight). For example, in NHANES I, people living in poverty census enumeration districts were sampled as much as eight times more often than people living elsewhere. Additionally, persons aged 65 years or older were sampled twice as often as women ages 20–44, who in turn were sampled twice as often as other adults.

TABLE 2—Adjusted Mean Values[a] for Total Iron-Binding Capacity for Subjects in Whom Cancer Developed and Those Who Remained Cancer-free

	Clustering Used?	Sample Weights Used?	Cancer[b]	No Cancer[c]	Difference		
					Mean±SE	95% CI	P
				Men			
A[d]	No	No	61.30	62.78	−1.48±0.60	−2.65 to −0.31	.013
B	No	Yes	62.65	63.57	−0.92±1.06	−2.99 to 1.15	.38
C[e]	Yes	No	61.30	62.78	−1.48±0.54	−2.58 to −0.38	.010
D[e]	Yes	Yes	62.65	63.57	−0.92±0.86	−2.67 to 0.83	.29
E	Yes	Partly[f]	62.07	63.51	−1.44±0.53	−2.51 to −0.37	.010
				Women			
A[d]	No	No	66.32	66.40	−0.08±0.79	−1.62 to 1.46	.92
B	No	Yes	65.60	66.32	−0.73±1.18	−3.04 to 1.58	.54
C[e]	Yes	No	66.32	66.40	−0.08±0.69	−1.48 to 1.33	.91
D[e]	Yes	Yes	65.60	66.32	−0.73±1.29	−3.34 to 1.88	.58
E	Yes	Partly[f]	66.20	66.35	−0.16±0.60	−1.38 to 1.06	.82

Note. SE = standard error; CI = confidence interval.

[a] Means are adjusted for age and smoking status. For the analysis labeled E, means are also adjusted for race (White vs non-White), family income (<$3000, $3000–$6999, $7000–$9999, $10 000–$14 999, ≥$15 000), poverty vs nonpoverty census enumeration district, and senior status (age ≥65 or <65). For the 3.8% of the sample whose family income was unavailable, income was imputed from education of the head of household in the same manner used in the construction of the sample weights.

[b] For men, N = 242; for women, N = 203.

[c] For men, N = 3116; for women, N = 5165.

[d] Analyses labeled A are from Stevens et al.[41] Adjusted means for cancer and no cancer groups are slightly different here because their analysis implicitly assumed that all four smoking categories were equally likely. Analyses here use observed proportions in each smoking category (analyses A and B) or estimated population proportions in each category (analyses C, D, and E).

[e] Mean estimates for analysis C and D are the same as estimates for analysis A and B, respectively.

[f] Analyses labeled E are unweighted regressions with means adjusted for many of the variables used in defining sample weights (see footnote a).

Finally, in a small number of segments there were more households encountered by the interviewers than expected. These households were subsampled at rates of one half to one quarter.

The second component of the sample weight is an adjustment for nonresponse, including both the inability to locate sampled individuals and their refusal to participate. Although there is no ideal approach to adjust for nonresponse, adjustment using weights is as follows. The population is divided into groups so that the probability of nonresponse is thought to be roughly similar for all individuals within a group. The data from respondents is then weighted upwards depending on the nonresponse rate of their corresponding group. For example, in NHANES I the nonresponse groups were based on five family income groups within each PSU.

The third component of the sample weight is an adjustment so that the sum of the weights for a given sex, race, and age agree with known population figures (poststratification adjustment). Finally, because not all sampled persons in NHANES I had their body iron stores measured, a special set of weights was derived for use in the analysis of these data.

Reanalysis of the Body Iron Stores-Cancer Association

In this section we follow the analyses given in Stevens et al.[41] with the exception of using the sample clustering and/or the sample weights. We demonstrate how the conclusions of the analysis change when these two aspects of the sampling design are incorporated. We restrict attention to the associations described by Stevens et al.[41] of total iron-binding capacity (mol/L) and transferrin saturation (%) with the development of cancer. Briefly, the data to be analyzed are from 3358 men and 5368 women who (1) had their total iron-binding capacity measured in NHANES I in 1971–1975, (2) had their cancer status determined in the follow-up survey in 1981–1984, and (3) were alive and cancer-free for at least 4 years after their biochemical measurements. These sample sizes are slightly different from those of Stevens et al.[41] because the follow-up public use data files have been revised since their analyses.

Although there are many ways to analyze this type of follow-up data, we follow the simplest analysis given by Stevens et al.,[41] which compares the mean biochemical values in those respondents who developed cancer and those who did not, adjusted by linear regression for age (years) and smoking status (current smoker, former smoker, never a smoker, and unknown). Tables 2 and 3 contain the results of five different analyses of these same associations, labeled A through E.

The A analyses repeat the Stevens et al.[41] analyses. We conclude from the A analyses that for both variables there is a small but statistically significant association for men and no association for women.

The B analyses use the sample weights of the survey but not the clustering. A dramatic effect of using the weights is the increase in the standard errors (SEs), the most extreme case being the change from 0.79 to 2.53 for the SE of the difference in adjusted means for the women's transferrin saturation. The correct interpretation for this particular weighted analysis is not that there is no association between transferrin saturation and the development of cancer in women. Instead, it is that because the SE and confidence interval (CI) are so large, the data on the association are uninformative.

The C and D analyses use the sample clustering, without and with the sample weights, respectively. Only the SEs, not the means, are possibly affected by use of the clustering. For these particular analyses, it turns out that the standard errors are not much affected. The results and conclusions, therefore, are very similar to the unclustered A and B analyses, respectively.

We recommend the E analyses for several reasons. They are unweighted analyses that use the sample clustering, but for which the adjusted means have been further adjusted by linear regression for many of the variables used in defining the sample weights (see footnote a of Table 2). The results and conclusions of the E analyses turn out to be very similar to the unweighted unclustered A analyses. This happens to be true even though these analyses do not ignore the sampling weights and clustering.

The computer programs REG[63] and SURREGR[64] were used to perform the analyses A and B–E, respectively. Because 3 of the PSUs have no total iron-binding capacity data available, for the C, D, and E analyses the strata containing these PSUs are pooled with neighboring strata to yield a design approximated by 67 PSUs selected from 32 strata. The analyses A–E give an idea of the different conclusions that are possible when using various aspects of the sample design in the analysis. In the sections below, we give some rules of thumb for choosing the most appropriate analyses based on the sample survey design alone.

Should Sample Clustering Be Used in Analysis?

Sample clustering can affect the variability (SEs) of estimates of associations. First, a simple but extreme example will show this. Consider a simple random sample of 1000 households, where disease and risk factor status are obtained from each member of the household. Suppose that if one member of a household has the risk factor, then all members of the household have it, and if one member of the household has the disease, then all have it. The appropriate sample size for the analysis of this sampled data is 1000, not the number of individuals sampled. Thus, for example, if 4000 individuals had been sampled in the 1000 households, and the sample (household) clustering was ignored in the analysis, then SEs would be too small by a factor of 2 ($= \sqrt{4000/1000}$), because SEs are inversely proportional to sample sizes. Admittedly, this is an extreme example to make the point; in general the effect of clustering depends on both the cluster size and the intraclass correlation.[62]

TABLE 3—Adjusted Mean Values[a] for Transferrin Saturation (%) for Subjects in Whom Cancer Developed and Those Who Remained Cancer-free

	Clustering Used?	Sample Weights Used?	Cancer[b]	No Cancer[c]	Difference		
					Mean±SE	95% CI	*P*
				Men			
A[d]	No	No	33.15	30.73	2.42±0.78	0.89–3.94	.002
B	No	Yes	32.55	30.43	2.12±1.48	−0.78–5.03	.15

D[e]	Yes	Yes	32.55	30.43	2.12±1.22	−0.35–4.59	.09
E	Yes	Partly[f]	32.92	30.48	2.44±0.85	0.71–4.17	.007
				Women			
A[d]	No	No	27.98	27.17	0.81±0.79	−0.73–2.36	.30
B	No	Yes	31.37	27.74	3.63±2.53	−1.32–8.58	.15
C[e]	Yes	No	27.98	27.17	0.81±0.76	−0.72–2.35	.29
D[e]	Yes	Yes	31.37	27.74	3.63±2.42	−1.28–8.53	.14
E	Yes	Partly[f]	28.36	27.57	0.78±0.74	−0.72–2.28	.30

Note: SE = standard error; CI = confidence interval.

[a] Means are adjusted for age and smoking status. For the analysis labeled E, means are also adjusted for race (White vs non-White), family income (under \$3000, \$3000–\$6999, \$7000–\$9999, \$10 000–\$14 999, ≥\$15 000), poverty vs nonpoverty census enumeration district, and senior status (age ≥65 or <65). For the 3.8% of the sample whose family income was unavailable, income was imputed from education of the head of household in the same manner used in the construction of the sample weights.

[b] For men, N = 232; for women, N = 197.

[c] For men, N = 3058; for women, N = 5073.

[d] Analyses labeled A are from Stevens et al.[41] Adjusted means for cancer and no cancer groups are slightly different here because their analysis implicitly assumed that all four smoking categories were equally likely. Analyses here use observed proportions in each smoking category (analyses A and B) or estimated population proportions in each category (analyses C, D, and E).

[e] Mean estimates for analysis C and D are the same as the estimates for analysis A and B, respectively.

[f] Analyses labeled E are unweighted regressions with means adjusted for many of the variables used in defining sample weights (see footnote a).

In many realistic situations, the "disease" may be a continuous outcome (e.g., blood pressure) and the risk factor may also be a continuous variable (e.g., dietary calcium intake). Additionally, the risk factor-disease association of interest may be the one in which certain covariates are controlled for, e.g., sex and age. A general sufficient condition for ignoring the clustering in the analysis is the distribution of the outcome for given levels of the risk factor and covariates does not depend on which cluster the individual is in. Given the complicated multistage sampling in a survey such as NHANES I, it may not be obvious whether this condition is satisfied or not.

Since adjusting for the sample clustering will on average increase the SEs, its use in the analysis can be thought of as a conservative procedure. What is lost by using the clustering in the analysis when it was unnecessary? Unnecessary clustering leads to an inefficient analysis, that is, an analysis with CIs wider than necessary and with less statistical power for rejecting the null hypothesis. An easy way to express this inefficiency is in terms of relative sample sizes. For example, an analysis that is 20% inefficient with respect to another analysis means that a sample size of 1000 in the inefficient analysis is equivalent to a sample size of 800 in the more efficient analysis. A key number for estimating the inefficiency of using clustering when unnecessary is the degrees of freedom, d, available for the estimation of SEs. The d is usually taken to be the number of sampled PSUs minus the number of strata. For example, in the NHANES I analysis of body iron stores and cancer, d = 35 = 67 − 32.

The approximate inefficiency in doing an analysis that uses the sample clustering when unnecessary is:[65]

$$\text{Inefficiency} = 1 - (z^{1-\alpha/2}/t_d^{\,1-\alpha/2})^2$$

where $z^{1-\alpha/2}$ and $t_d^{\,1-\alpha/2}$ are the $1 - \alpha/2$ percentiles of a normal distribution and a t-distribution with d degrees of freedom, respectively, and α is the significance level for testing or one minus the confidence level for CIs. For example, for the analyses of NHANES I given in the previous section in which we used 95% CIs for the mean differences, suppose we are also interested in hypothesis testing at the $\alpha = .05$ level. Because d = 35, any standard set of statistical tables gives $z^{0.975} = 1.96$ and $t_{35}^{\,.975} = 2.03$. The inefficiency equals 6.8%, an inefficiency so small that one should use the clustering in the analyses. If the clustering is important, it must be used so that the variability of means is properly estimated; if the clustering is unimportant, little is lost by using it unnecessarily. The similar magnitude of the SEs for analyses A and C in Tables 2 and 3 suggest that, in fact, clustering was not important for these data.

In general, the inefficiency of using the sample clustering when unnecessary becomes greater with decreasing degrees of freedom. For example, the design of HHANES can be approximated[66] by sampling 16 PSUs from 8 strata. For this design, the inefficiency is 28% when the clustering is unnecessary (using d = 8 in the above formula), making the decision of whether or not to use the clustering in the analysis more difficult than with NHANES I. These inefficiency calculations are meaningful whenever a single disease-risk factor association is being examined. For simultaneous analysis of many disease-risk factor associations or other multivariate analyses, the inefficiency of using the clustering when unnecessary can increase.[67]

Should Sampling Weights Be Used in Analysis?

It is well known that the unweighted mean of a sample that is not a simple random sample can lead to a biased estimate

TABLE 4—Percentiles of Sample Weights for Individuals Analyzed

Sex	Minimum	5%	25%	Median	75%	95%	Maximum
Men (n = 3358)	477	876	3614	8170	19 504	31 556	135 824
Women (n = 5368)	611	114[illegible]	3162	6684	11 119	24 090	186 062

of the population mean, whereas a weighted mean provides an approximately unbiased estimate. It is not as obvious that an unweighted analysis of a disease-risk factor association can also lead to the wrong conclusions. A simple numerical example given in the Figure shows this to be true. The expected numbers of sampled individuals are given in the Figure for two sampling schemes for the whole population was well as within two subgroups defined by area of residence. On the left, a study using a simple random sample of 10 000 individuals would show on average the correct result that an association exists between the disease and the risk factor: The probability of having the disease is 5.9% without the risk factor and 12.2% with the risk factor, for a relative risk of approximately 2. On the right, a study of the same population that samples nonurban area residents at nine times the rate of urban area residents would on average sample the same number of individuals from each type of area. Unweighted analysis of data from this probability sample suggests incorrectly that there is no association between the disease and the risk factor. A weighted analysis of the data from this probability sample would on average yield the correct association:

$$2.06 = \frac{(9\times245 + 655)/[(9\times245 + 655) + (9\times4655 + 3445)]}{(9\times15 + 85)/[(9\times15 + 85) + (9\times85 + 815)]}$$

A weighted analysis will provide an approximately unbiased estimate of the population association, whereas an analysis ignoring the weights, in general, will not. A general sufficient condition for when the sampling weights can be ignored, however, is as follows: The distribution of the outcome (disease) for given levels of the risk factor and covariates does not depend on any variables used in the sampling design or used to adjust for nonresponse.

Because it may be difficult to verify this sufficient condition, what is the harm in always using the sample weights in the analysis? As with the use of clustering when unnecessary, the use of sampling weights when unnecessary leads to an inefficient analysis. This inefficiency can be defined as

$$1 - (SE_{unwtd}/SE_{wtd})^2$$

where SE_{unwtd} and SE_{wtd} are the unweighted and weighted SEs of the mean difference. For the linear regression models used in the analyses here, the calculation of the efficiency depends on the distribution of the sample weights and independent variables (see DuMouchel and Duncan[68] for the exact formulas). An approximation is given by the following formula:

$$\text{Inefficiency} = 1 - (w_1 + w_2 + \ldots + w_N)^2/[N(w_1^2 + w_2^2 + \ldots + w_N^2)]$$

where $w_1, w_2, \ldots, w_N$ are the sample weights for the N sampled individuals. The inefficiency increases when the sample weights are more variable, and is zero if all the sample weights are identical.

Table 4 presents selected percentiles of the distribution of sample weights for the individuals analyzed here. The range of the weights is very large, with the largest weight 285 (300) times greater than the smallest weight for the men (women). The inefficiencies of using the sample weights when unnecessary are calculated to be 47% and 48% for men and women, respectively. Considering that the unweighted SEs are not insubstantial compared to clinically meaningful treatment differences, these inefficiencies are too large for us to assert that little is lost by using the weights when unnecessary.

There is an additional consideration when using the sample weights in the analysis. If the sample weights do matter, they can make the analysis even less efficient than described above. For example, consider the analysis of the transferrin saturation in women given in Table 3. Comparing analysis A to analysis B, the SE has increased by a factor of 3.2 = 2.53/0.79, suggesting an inefficiency of 90%. A closer look at the data for this analysis is instructive. Out of the 197 women who developed cancer, the woman with the highest transferrin saturation (68.4%) also had the third largest sample weight (103 042) out of all 5368 women. If this woman's sample weight had had a median value of 6684, then the mean difference in the weighted analysis B would have been 1.35 ± 1.16 instead of 3.63 ± 2.53.

Since the inefficiency of performing a weighted analysis is unacceptably high, what do we recommend? One approach is to use an unweighted analysis but to control for the variables utilized in determining the sample weights. In the present context, the E analyses in Tables 2 and 3 compute the means adjusted for many of these variables. One could argue[69] that because these additional variables (family income, race, etc.) are highly unlikely to be on the causal pathway between body iron stores and the development of cancer, it would be useful to control for these variables even if we had a simple random sample. We view this not as the perfect solution, but as a compromise that avoids the inefficiency of a weighted analysis. As it happens, the results of the E analyses are remarkably similar to the unweighted, unclustered A analyses, but, we can now have more confidence in these results. However, for other data sets and other associations this may not be the case.

Discussion

The impact of sampling design on the analysis of complex survey data should always be considered. Which particular aspects of the design to use in the analysis, however, is a subtler question. Classical survey analysts recommend using both the clustering and the sample weights in the analysis.[70,71] Although this is a philosophically defensible position, we have seen above that it can lead to inferences that make the whole study worthless. On the other hand, the position of Stevens et al.[55] that the sampling design can be ignored when addressing these types of questions is tenuous unless one is willing to make strong assumptions. We have attempted in this article to give simple ways of weighing the costs and benefits of accounting for the sampling design in the analysis. For specific recommendations concerning sample clustering and sample weights, we offer the following rules of thumb.

(1) If the number of sampled PSUs minus the number of strata is greater than or equal to 20 (corresponding to an inef-

ficiency of roughly 10%), then use the clustering in the analysis. Otherwise, more advanced statistical methods[72] to account for the clustering can be applied to roughly approximate the SEs of the parameters of interest.

(2) Calculate the approximate inefficiency of including the sample weights using the simple formula given in the previous section. If this inefficiency is less than 10%, then use the sample weights in the analysis. If this inefficiency is greater than 10%, then consider the effect this inefficiency will have on the SEs compared to an expected clinically meaningful treatment difference. If the effect is not unacceptably large, use the sample weights in the analysis. Otherwise, use an "unweighted" analysis that controls for the variables relating to the design and nonresponse adjustments in the analysis.

We end with two suggestions for the designers and producers of large-scale health surveys that will be used by other investigators. If our recommendations are followed, one will sometimes need to use variables relating to the design and nonresponse adjustments of the survey. Our first suggestion is that all these variables be documented and included in public use data files.

Our second recommendation concerns the design of the surveys themselves. As we have discussed, a small number of sampled PSUs or individuals with extremely high sample weights can make the use of the sample design in the analysis very inefficient. Given the large number of secondary analyses that are performed using these survey data, we suggest that policymakers provide sufficient resources so that the surveys can be designed for efficient secondary analyses using the design. ☐

Drug with Potential for Treating the Neuropsychological Effects of HIV Infection to Be Tested

The National Institute of Mental Health (NIMH) today announced the beginning of a clinical study of the effectiveness of Peptide T, a drug of potential value in treating the neuropsychological effects of HIV infection and AIDS.

"This is the first study designed to answer questions about the effectiveness of Peptide T by comparing the compound with a placebo in a controlled study design," said Alan I. Leshner, PhD, NIMH acting director.

The first patient started treatment with Peptide T in mid-March. The study, which is jointly sponsored by NIMH and the National Institute of Allergy and Infectious Diseases, is being conducted at the University of Southern California in Los Angeles.

The human immunodeficiency virus is believed to cause problems of concentration and memory in some persons with AIDS and AIDS-related complex by directly affecting the brain.

Peter N.R. Heseltine, MD, the principal investigator, said "in earlier studies, people with these problems have shown improvement in tests of their mental function when they were treated with Peptide T. The purpose of this new study is to discover if Peptide T is safely able to reduce these HIV-caused problems of concentration and memory and if it is safe and effective when used with the antiretroviral AZT (zidovudine)."

Ellen Stover, PhD, director of the NIMH Office of AIDS Programs, said, "this is the first time that a trial of an AIDS therapeutic will be using improvement in mental functioning as the key outcome. We are working toward making progress in treating HIV infection and are looking forward to the collaboration with USC investigators and the results of this study."

Peptide T was developed by NIMH scientists working at the institute's research facilities on the National Institutes of Health campus in Bethesda, Md. The peptide is an artificially produced protein that blocks the attachment of the AIDS virus to human cells by occupying receptors on the cell surface. Its structure is similar to part of the protein coat of HIV.

In the Phase II study, a minimum of 150 men and women who have been infected with HIV will be enrolled in the double-blind, placebo-controlled trial. (Phase II studies are designed primarily to test the efficacy of new therapies.)

The investigators are making special efforts to enroll women and minorities, who have been underrepresented in some earlier AIDS studies.

Initially, participants will receive either Peptide T or placebo for 6 months, and then during the second 6-month period, all study participants will receive the peptide. During the 1-year study, participants may take any medications approved by the Food and Drug Administration for preventing AIDS-related opportunistic infections, and they may continue treatment with antiviral therapies if they are taking them when they enter the study.

Individuals interested in participating in the study should call Charles Hovis, LAC-USC Medical Center, 213/226-4643, or the PHS-sponsored AIDS Clinical Trials Information Service, 1-800-TRIALS-A.

Breast Cancer Screening among Relatives of Women with Breast Cancer

Karen M. Kaplan, MD, Gene B. Weinberg, DrPH, Alden Small, PhD, and Joy L. Herndon, MS

ABSTRACT

Background. National surveys indicate that only 15% to 30% of all women in the general population 50 years of age or older have an annual mammogram.

Methods. We studied first-degree female relatives of women with breast cancer, who are at elevated risk of disease, to describe the breast cancer screening practices of these relatives and to improve their practices through a program of intensive education. We report here the screening behaviors of 2471 relatives of women with breast cancer.

Results. Self-reported behaviors were as follows: 49% performed monthly breast self-examination and 70% had annual breast examinations by a medical professional. Of 983 women 50 years of age or older, 49% had had a mammogram, but only 14% have a mammogram annually. Of women 50 years of age or older who had never had a mammogram, 92% reported never having had one recommended by a medical professional.

Conclusions. Our findings indicate that screening behaviors in relatives of breast cancer patients are not substantially different from those of women in the general population. Enhanced efforts both to educate medical professionals and to encourage women to demand screening mammography are necessary to reduce breast cancer mortality. (*Am J Public Health.* 1991;81:1174–1179)

Introduction

Nearly one in nine women in the United States will have breast cancer in her lifetime. An estimated 175 000 new cases will be diagnosed and an estimated 44 500 deaths from this disease will be recorded during 1991. Breast cancer ranks second only to lung cancer as a cause of cancer mortality in women; yet despite biomedical advances in breast cancer therapy, mortality has remained fairly constant and has even increased slightly in recent years.[1]

Routine breast examination by a physician and breast self-examination (BSE) both have been shown to be more effective than accidental discovery in detecting the disease at an early stage.[2,3] Moreover, detection of early lesions using a combination of professional breast examination and mammography for women ≥50 years of age, and more recently for women 40 to 49 years of age, has been shown to improve survival from breast cancer.[4]

Despite the potential reduction in morbidity and mortality using available breast cancer screening methods, screening measures are underutilized. Recent population-based surveys indicate that 50% of women ≥50 years of age perform monthly BSE, 50% have annual professional breast examinations, and no more than 15% to 30% have annual mammograms.[5-8]

A total of 8% of women 40 years of age or older in the United States have at least one first-degree female relative (mother, daughter, or sister) who has had breast cancer.[9] Nevertheless, little is known about the screening behaviors of these relatives,[10-12] women whose risk of disease is estimated to be twofold to fourfold higher than that for women in the general population.[13] Krischer and colleagues studied the breast cancer screening behaviors of 138 first-degree and 70 second-degree relatives of women with breast cancer and found low prevalence rates of breast cancer screening overall, rates comparable to those of women in the general population.[10] To further investigate this group of high-risk women, the Pennsylvania Cancer Program of the Pennsylvania Department of Health supported six pilot projects from 1984 to 1987. The projects were designed to identify relatives of women with breast cancer, to describe the breast cancer screening behaviors of these relatives, and to improve their behaviors through a program of intensive education.

We report here the screening behaviors of these relatives in five of the pilot projects. We hypothesized that health care providers would more effectively screen women who were known to be at elevated risk of breast cancer and that the prevalence of screening behaviors among this population would be higher than that among women in the general population.

Karen M. Kaplan and Joy L. Herndon were with the Epidemiology Program Office, Centers for Disease Control, Atlanta, Ga. Gene B. Weinberg and Alden Small are with the Pennsylvania Department of Health, Harrisburg, Pa. Dr. Kaplan is now with the Department of Pediatrics, The Pennsylvania State University College of Medicine, Hershey, Pa.

[a] Data are not available for all behaviors stratified by all characteristics.
[b] Biennial mammograms in women 40–49 and annual mammograms in women ≥50.
[c] Women ≥40 only.
[d] Women 35–39 only.
[e] NA = not applicable.

Methods

All women diagnosed with breast cancer from 1980 to 1986 were identified from cancer registries in eight Pennsylvania hospitals and from the Pennsylvania Cancer Registry in the south-central region of the state. Only women known to be alive at the time of the study were included. The physician who completed the cancer registry data form was contacted for permission to contact the patient; women whose physicians granted permission received letters describing the study and inviting their participation. Women with breast cancer were asked to identify and give permission to contact their mothers, sisters, and daughters, ≥18 years of age, for enrollment in the study.

Data were collected either by telephone or in face-to-face interviews using a structured questionnaire that included demographic characteristics and information about three breast cancer screening behaviors: performance of BSE, breast examinations by a medical professional, and mammography. All information was self-reported; no attempt was made to verify the reported frequencies of screening behaviors by review of medical records.

Because the majority of participating relatives lived in the area of the hospital and because no specific information on residence was collected, the catchment area of the hospital was used as a surrogate for characterizing residence.

The Statistical Analysis System (SAS Institute, Cary, NC) was used for data analysis. Categorical data were compared using χ^2 and the χ^2 test for trend. In reporting stratified data on screening behaviors, only participants with complete risk factor and outcome information were included. To compute the odds ratio for each of the three screening behaviors while simultaneously controlling for the potentially confounding effects of other characteristics, we used unconditional logistic regression (SAS CATMOD with the CLOGITS option).

Results

Demographics

A total of 4012 women with histologically confirmed breast cancer were identified. At the time of the study, 3229 were still alive and were well enough to participate. The physicians of 2975 (92%) of these gave consent for their patients to be contacted. A total of 2050 women (64%) agreed to participate, and 1862 (58%) were interviewed.

Women with breast cancer identified 3860 relatives, of whom 2865 (74%) were invited to participate. A total of 2540 relatives (66%) agreed to participate, and 2539 were interviewed. Data on 68 of these women (2% of the total group of relatives) who reported that they also had had breast cancer were excluded from the analysis. The analysis thus consists of 2471 women, 64% of the relatives of participating women with breast cancer.

Characteristics of participating relatives are summarized in Table 1. The majority were <50 years of age, White, had completed at least 12 years of education, and had a household income >$20,000. A total of 44% of participants were from urban areas, 51% were from areas of mixed type (urban and rural), and 5% were from rural areas. Information about relatives who declined to participate was not available.

Screening Behaviors

A total of 83% of women have done BSE, and 96% have had at least one breast examination by a medical professional (Table 1). A total of 42% of women 35 to 39 years of age, 53% of women 40 to 49 years of age, and 49% of women ≥50 years of age have had at least one mammogram. A total of 28% of women ≥50 years of age reported having had a mammogram within the previous 12 months.

In order to more accurately distinguish routine screening behaviors from breast examinations or mammography done because of breast abnormalities, we also examined periodic performance of breast cancer screening. Table 1 shows the proportions of women reporting monthly BSE, annual breast examinations from a professional, periodic mammography (biennial mammograms for women 40 to 49 years of age and annual mammograms for women ≥50 years of age) for women overall and stratified by age, race, residence, relationship, education, and income. Younger women, women from urban areas, daughters of women with breast cancer, more highly educated women, and women of higher income more often performed monthly BSE, had annual breast examinations from a professional, and had periodic mammography. Although the numbers of non-White

[a]Includes physicians of unknown specialty, surgeons, and oncologists.

women in the study population were small, White women performed BSE and had periodic mammography more frequently. Non-White women more frequently had annual professional breast examinations.

Medical Care Encounters

Of 700 women >40 years of age who had never had a mammogram, 89% reported that a mammogram had never been recommended to them by a medical professional. Stratified by age, 83% of women ages 40 to 49 and 92% of women ≥50 years of age reported never having had a mammogram recommended.

The 75 women who had never had a mammogram, but to whom a mammogram had been recommended, were asked why they had not had one. A total of 19% responded "no particular reason," 17% cited high cost as the primary reason, and 13% said that they planned to have a mammogram.

Of 959 women ≥50 years of age for whom information was available, 67% had had a professional breast examination within the previous 12 months. Of these women, 41% had had a mammogram within that period of time compared with 2% of women who had not had a breast examination within 12 months ($\chi^2 = 163.58$; $P < .001$) (Table 2). Nevertheless, 59% of women who had had a breast examination by a professional within the previous 12 months had not had a mammogram within that period of time.

In the same group of 959 women ≥50, we noted the type of medical specialist usually seen for a breast examination stratified by mammography use and annual mammography use (Table 3). A total of 60% of women who usually have a breast examination by an obstetrician/gynecologist had had a mammogram, compared with 57% seen by internists and 39% who usually have breast examinations by a general practitioner (χ^2 for trend = 34.31; $P < .001$). Moreover, only 8% of women usually seen by a general practitioner for breast examinations have annual mammograms, compared with 21% seen by obstetrician/gynecologists and 24% seen by internists ($\chi^2 = 28.24$; $P < .001$). Some women were seen for breast examinations by surgeons, oncologists, or physicians whose specialties were unknown or unreported. These medical practitioners make up the "other" category. The extent to which the practices of physicians in this category are comparable is not known. The differences by medical specialty persisted when the data were stratified by age groups, education groups, and income groups. When we stratified the data by residence, we found the same differences in mammography use based on the type of physician seen for a breast examination among residents of both urban and mixed (urban and rural) settings. There were too few observations for women living in rural areas to make meaningful comparisons among the three types of residences, however.

Multivariate Analyses

We examined BSE, breast examination by a professional, and annual mammography using unconditional logistic regression. The importance of age, income, education, urban setting, family relation, and type of medical professional seen for a breast examination were all analyzed in connection with the three outcome behaviors mentioned above (Table 4). Controlling for the other variables in the model, monthly BSE was significantly associated with urban residence. For the outcome of annual breast examination by a professional, the variables of most importance when controlling for other factors were younger age, higher income, urban residence, and type of medical professional seen for a breast examination. (Women usually seen by obstetrician/gynecologists were more likely to have annual examinations than women seen by general practitioners.) When these same independent variables were analyzed with annual mammograms as the outcome variable, older age, higher income, urban residence, and type of medical professional seen for a breast examination were the variables of most importance. Women usually seen by obstetrician/gynecologists, internists, or physicians in the "other" category were more likely to have annual mammograms than women usually seen for breast examinations by general practitioners.

Adherence to American Cancer Society Screening Guidelines

We examined the behaviors of women in the two age groups 40 to 49 and ≥50 to determine what proportions adhere to American Cancer Society (ACS) guidelines: monthly BSE; annual breast examinations by a professional; and mammography, biennially for women 40 to 49 and annually for women ≥50 years of age.[14] Seventeen percent of women ages 40 through 49 have biennial mammograms, and 14% of women ≥50 have annual mammograms (Table 1). A total of

TABLE 5—Prevalence of Breast Self-Examination (BSE), Professional Breast Examination (BE), and Mammography (MAM), Pennsylvania, 1984–1987, vs Studies of Women in the General Population

Behavior	Percentage Pennsylvania	Percentage General Population
Monthly BSE	49	47–50[5,9]
Annual BE	70	50–55[5–7]
MAM[a]	50	40–67[7–9,16]
Annual MAM[b]	14	15–30[6–8]
MAM ≤1 yr[b]	28	20–41[7,15,17,21]

[a] Women ≥40 years of age.
[b] Women ≥50 years of age.

41% of women 40 to 49 and 32% of women ≥50 adhere to the recommended screening for two of the three practices, monthly BSE, and annual professional breast examinations. Only 11% and 8%, respectively, adhere to all three screening guidelines for their age group.

We compared our findings with those of other surveys of breast cancer screening among women in the general population (Table 5). The prevalence of monthly BSE and mammography use reported in our study is similar to that of women in the general population.[5–8,15–19] The prevalence of annual professional breast examination, 70%, is higher than generally reported.[5–7,9] The proportion of women in the general population who practice a combination of these three screening methods is not known.

Discussion

Our findings indicate that BSE and mammography use in relatives of women with breast cancer, who are at elevated disease risk, do not differ substantially from the behaviors of women in the general population. Despite the higher rates of professional breast examinations reported for this population, barriers to more widespread use of screening mammography exist. Our data do not support the hypothesis that physicians screen selectively and comprehensively those women known to be at elevated risk of breast cancer. Nearly 90% of women who had never had a mammogram reported that a medical professional had never recommended one.

Older women, women of lower socioeconomic status, and women living in rural areas were less likely to report adherence to current ACS breast cancer screening guidelines. Similar risk factors for inadequate preventive health practices in general and for breast cancer screening in particular have been found in national surveys.[9,19–21]

Not surprisingly, we found that women who reported having had a recent professional breast examination more often reported having had a recent mammogram. Yet the majority of women ≥50 seen for a breast examination within the previous year who would have been eligible for screening mammography were not screened, most often because their physicians had not recommended it.

We found differences in compliance with guidelines for mammography use among medical specialties: women who usually had breast examinations by internists or obstetrician/gynecologists were more likely to have mammograms than women who usually had breast examinations by general practitioners. Reasons for the apparent differences in practices among medical specialists are not clear, but such differences may in part reflect type or recency of medical training or participation in continuing medical education. It is also not known whether women in the study population who have breast examinations by general practitioners were less likely to have health insurance that covers screening mammography than were women seen by internists or obstetrician/gynecologists. Bergner and colleagues[22] found that recent medical school graduates and medical school faculty members were more likely to perform a series of cancer screening procedures among asymptomatic patients over the age of 50 for whom they provided primary care. In their survey, obstetrician/gynecologists followed by oncologists most often performed breast examinations and screening mammograms. Information on years since graduation from medical school or faculty status was not available for the physicians of participants in our study.

The failure of physicians to follow established guidelines for breast cancer screening in asymptomatic women was documented in a 1989 Ohio survey of more than 1000 practicing primary care physicians.[23] The survey found that although 98% advise their patients to do BSE, and 78% followed published ACS guidelines for periodic breast physical examinations, only 37% followed guidelines for screening mammograms in asymptomatic women.[23] A similar survey conducted in 1984 found 80% and 11% of physicians adhering to ACS guidelines for breast physical examinations and screening mammography, respectively.[24]

The National Cancer Institute (NCI) has developed the following objective for breast cancer screening for the year 2000: 80% of women 50 to 70 years of age will have both annual breast examinations by a medical professional and annual mammograms.[25] The authors of *Healthy People 2000* suggest that the NCI breast cancer screening goals be incorporated into the Nation's Year 2000 Health Objectives.[26] To achieve these goals, enhanced educational efforts are needed, particularly in promoting mammography. These efforts should target both primary health care providers and women ≥50 years of age. Medical school, residency training, and continuing medical education programs should include instruction on the current approaches to breast cancer screening. The 1989 survey of practicing primary care physicians suggested that misinformation about radiation risks from mammography may deter some physicians from ordering screening mammograms for their patients.[23] In addition, women should be encouraged to demand screening mammography, an approach that has shown utility in stimulating physicians to provide other preventive services.[27–29]

Several limitations of the study design should be noted. First, participation rates were low for women with breast cancer (58%) and their relatives (64%); yet there was no information by which to compare characteristics of participants and nonparticipants. We believe that nonparticipants are unlikely to have better screening behaviors than participants.

Second, in order for women with breast cancer to provide access to their relatives, only those women still alive at the time of the study were eligible breast cancer patients. Whether relatives of women who have died from breast cancer differ from other relatives in their screening behaviors is not known. Further research is needed to better understand factors such as stage of disease at diagnosis, extent of disease, or type of therapy, all of which may affect preventive behaviors in asymptomatic relatives.

Third, all information in the study was self-reported and thus subject to recall bias on the part of the respondents. No attempt was made to verify the reported frequency of professional breast examinations or mammography use by review of medical records. It is therefore possible that some groups of women are more likely to recall breast cancer screening practices better than others.

Fourth, the population studied was primarily White and of relatively high socioeconomic status; the findings may be neither comparable to findings of other population surveys of breast cancer screening behaviors nor generalizable to all populations. Additional studies should focus on the breast cancer screening practices of non-White women and women of lower socioeconomic status who are at elevated risk of breast cancer.

Despite these limitations, our data confirm the findings of previous surveys of women's breast cancer screening behaviors: screening remains underutilized.[5–9,15–18] Whether any of these surveys, including our own, actually measure women's behaviors as opposed to those of their health care providers is not clear. In either case, intensified efforts are needed to enhance the early detection of breast cancer in order to reduce mortality from this disease. ☐

New Insights into Sudden Infant Death Syndrome

Results from a study published in the May 1 *American Journal of Epidemiology* suggest that certain labor and delivery events may increase the risk of sudden infant death syndrome (SIDS).

SIDS is the leading cause of mortality in the United States for infants 1 to 12 months old, accounting for one to three deaths per 1000 live births. SIDS has been called "a diagnosis of exclusion" because its victims can only be identified through an autopsy that rules out all other explainable causes of death.

This study "is one of the first analytic studies to focus on the intrapartum period and risk factors for SIDS," says lead author Germaine M. Buck, PhD, clinical assistant professor, Department of Social and Preventive Medicine, School of Medicine and Biomedical Sciences, Buffalo, NY.

Buck and her team found a sevenfold increased risk for SIDS associated with vaginal breech delivery and more than twice the risk for SIDS when mothers were in labor 16 hours or longer. Their study population was selected from a 1974 cohort of live births from Upstate New York that included 132 948 resident mothers. Data were abstracted from hospital delivery and vital records for 148 autopsied cases and 355 matched controls.

"The majority of breech SIDS infants were single footling deliveries (a rarer type of breech presentation with the baby emerging one foot first). The more common form of breech delivery called 'frank' presentation, with the baby emerging buttocks first, was not associated with an increased risk for SIDS," Buck says.

"We suspect that the single footling breech presentation may be an indicator for an earlier problem in the fetus' development, while a breech delivery, per se, is not the direct cause of the syndrome," she says. This speculation concurs with previous studies that have suggested SIDS victims may be compromised before birth. As Buck explains, "SIDS babies may have experienced a prior central nervous system insult in utero since they often show signs of subtle growth retardation, including reduced birth weight and length." These effects could be explained by altered blood flow or oxygen supply to the developing fetus, Buck says, but not by labor or delivery events.

"The association between long labor and SIDS must be viewed conservatively," Buck adds. "There is a lot of subjectivity in the woman's reporting of how long she has been in labor when she is first seen in the hospital."

According to Buck, the incidence of SIDS has not diminished as prenatal care has improved in the last several decades. "SIDS is a chief contributor to this nation's high infant mortality rate, and further effort to understand this syndrome should be a public health mandate," she says.

Factors Influencing the Formation of New Human Coronary Lesions: Age, Blood Pressure, and Blood Cholesterol

Wendy J. Mack, PhD, and David H. Blankenhorn, MD

ABSTRACT

Background. The Cholesterol Lowering Atherosclerosis Study, a controlled angiographic trial, has reported that new native coronary artery lesions are significantly reduced by aggressive blood lipid lowering therapy with colestipol plus niacin. To study factors relevant to primary atherosclerosis prevention, we have conducted an epidemiologic analysis of new native coronary lesion formation in placebo-treated patients.

Methods. Univariate and multivariate logistic regression procedures were used to examine age at entry into the study, number of years since bypass, body weight, diastolic and systolic blood pressure, plasma total cholesterol, triglycerides, HDL-cholesterol, LDL-cholesterol, non-HDL-cholesterol, and apolipoproteins A-I,B, and C-III.

Results. Significant univariate protective factors were older age ($P<.006$), reduction of total plasma cholesterol ($P<.040$), and systolic ($P<.024$) and diastolic ($P<.022$) blood pressure. Significant multivariate protective factors were older age ($P<.005$) and reduction in systolic blood pressure ($P<.021$). Blood pressure effects were not associated with use of specific antihypertensive agents.

Conclusions. These data provide additional support for the control of hypertension and reduction of blood cholesterol level for primary and secondary ischemic heart disease prevention. They also indicate the existence of a population at high risk for early coronary lesion formation and the need for improved means to identify such individuals prior to the onset of clinical manifestations of ischemic heart disease. (*Am J Public Health.* 1991;81:1180–1184.)

Introduction

CLAS (Cholesterol Lowering Atherosclerosis Study) was a randomized, placebo-controlled angiographic trial testing the hypothesis that blood lipid lowering with colestipol plus niacin would slow or reverse the atherosclerotic process. CLAS was a secondary prevention trial involving men, ages 40 to 59 years, who had had previous aortocoronary bypass surgery. CLAS angiograms were evaluated for vessel closure, changes in degree of stenosis, and formation of new lesions. We have previously reported significant treatment benefits in overall coronary status of both native vessels and bypass grafts, including reduction of formation of new lesions.[1] Following publication of CLAS results, angiographic trials testing nifedipine[2] and dipyridamole plus aspirin[3] have also reported reduced formation of new coronary lesions, which suggests that pathways early in atherogenesis may be beneficially modified by several different types of therapy. Studies of atherogenesis in animal models and cultured cell systems suggest a variety of ways in which factors initiating lesion formation might differ from those that cause progression of established lesions. The relationship of risk factors to prevalence of human coronary lesions[4] and change in established coronary lesions[5–20] has been extensively studied by angiography, but there are no risk analyses for new coronary lesion formation. To explore risk factor effects on human new coronary lesion formation we conducted an analysis of risk for disease with nondisease in placebo-treated CLAS subjects by comparing subjects who developed new coronary lesions with those who did not. The influence of diet on new lesion formation has been reported previously.[21] We now address the association of clinical variables with the development of new lesions.

Methods

Study Population

Subjects were nonsmoking males, ages 40 to 59 years, with progressive symptomatic atherosclerosis who had had previous coronary bypass surgery. Screening procedures, criteria for exclusion, standard visit protocols, and basic intervention goals were reported earlier.[22] One hundred eighty-eight subjects were randomized into two treatment groups of 94 each; 162 completed the study, 82 of whom were placebo-treated. Average age at entry of all placebo subjects was 54.5 ± 0.5 (SEM) and average blood pressure was 123 mm Hg ± 1.5 (SEM)/80 ± 1.0 (SEM). Thirty percent never smoked and 70% had quit smoking more than 6 months before trial entry. Twenty-four-hour urine specimens were examined for nicotine and cotinine every 6 months to monitor nonsmoking status. Dietary goals for the placebo group were as follows: total fat calories to provide 26% of energy, less than 5% of energy from saturated fatty acids, 10% of energy from polyunsaturated fatty acids, and less than 250 mg cholesterol per day. One-on-one diet counseling was conducted at each clinic

visit with a review of fat and cholesterol intake in computerized 7-day food records from the preceding week. Levels of physical activity were moderate as judged from questionnaires and estimates of energy expenditure from records of caloric intake for the 7 days preceding each clinic visit.

Data Collection

Angiographic. Baseline coronary angiography was performed immediately before randomization. A repeat angiogram was performed at 2 years by the same angiographer, who was blinded to the treatment assignment. Coronary angiogram evaluation procedures have been described in detail previously.[1,22] All lesions greater than 20% diameter stenosis were identified. Film pairs showing identical coronary artery views were mounted side by side on two Vanguard projectors and viewed simultaneously by two expert angiographers who did not know the subject's demographic and clinical characteristics, treatment assignment, or temporal order of the angiograms. The angiographers were not shown ventriculograms and other angiograms. Working independently, the two angiographers identified all visible lesions in one film (assigned at random), recorded this information, and then shared it to reach a consensus. In this manner a total of 1831 lesions were recognized and evaluated, 82% of which were identified independently by both panelists. For the 1501 lesions identified independently by both panelists, agreement within ±10% stenosis occurred in 76%. After reaching a consensus on the first film, panelists examined the second film alongside the first and compared all lesions first separately and then together. After all film pairs were evaluated, the code for film order was broken and lesions recorded in a later angiogram, but not in a first, were tabulated.

Body Weight, Blood Pressure, Plasma Lipids, and Medication History. Body weight, blood pressure, and plasma lipids were measured at every visit.[22] Blood lipids and lipoprotein cholesterol levels were determined by Lipid Research Clinics methodology standardized against reference materials supplied by the Centers for Disease Control.[23] LDL-cholesterol levels were calculated with the equation of Friedewald et al.[24] Baseline levels were the means of the first three screening visits. Postrandomization visits were scheduled every month for the first 6 months and bimonthly thereafter. On-trial values were the average of all postrandomization visits weighted by the scheduled interval between treatment visits. Apolipoprotein determinations were performed by the Oklahoma Foundation for Medical Research.[22] All medications, including over-the-counter drugs, were recorded at semiannual visits (0, 6, 12, 18, and 24 months after randomization).

At study entry 36% of the 82 CLAS placebo subjects reported use of antihypertensive medications and 93% of this group remained on these agents during the trial. The most common drugs and dosage were propranolol 40 mg/day (33% of subjects), hydrochlorothiazide 50 mg/day (13%), and dyazide 50 mg/day (10%). Eight percent of CLAS placebo subjects reported one or more on-trial uses of either nifedipine, diltiazem, or verapamil. Eighty percent of subjects took either aspirin, Ascriptin, or acetaminophen on one or more occasions during the trial.

Statistical Analyses. Univariate logistic regression procedures were used to determine which independent variables were predictive of the development of new lesions. Potentially predictive independent variables included age at entry into the study, number of years since bypass, body weight, diastolic and systolic blood pressure, plasma total cholesterol, triglycerides, HDL-cholesterol, LDL-cholesterol, non-HDL-cholesterol, and apolipoproteins A-I, B, and C-III. Age and years since bypass were analyzed by values at baseline. All other variables were analyzed by values at baseline, as well as mean on-trial, to explore the temporal relationship of these variables to lesion formation. In addition, the difference (baseline minus mean on-trial) was analyzed to assess the relationship between change in these variables and new lesion formation. We chose to compare baseline to mean on-trial values of each independent variable for two reasons. First, given the relatively small sample size of this study and the fact that each subject contributed a potential of 15 on-trial data points for each variable, it was not feasible to assess the significance of each variable at each time point. Second, given the short time period of this study (2 years) relative to the several decades of life, over which atherosclerotic disease develops, we felt that assessing the association of overall on-trial changes relative to prerandomization measures provided a more meaningful analysis. For each independent variable, univariate odds ratios (OR) and associated 95% confidence intervals (CI) were computed[25]; all *P* values for trends in relative risk are based on two-tailed tests. Stepwise logistic regression was used as a final step to arrive at a multivariate model of statistically independent predictors of new lesion formation.

Results

Of the 82 subjects in the placebo group, 18 had developed new lesions in the 2-year period between angiograms, as previously reported.[1] Thirteen among the 18 subjects with new lesions had a single new lesion, 3 had two new lesions, and 1 each had three and four new lesions. Among the 26 new lesions, 15 were in ungrafted patent arteries, 1 was proximal to complete occlusion in an ungrafted artery, 6 were proximal to open grafts, 2 were distal to open grafts, and 2 were distal to closed grafts. Nine of the new lesions were between 20% and 29% diameter stenosis and 6 were between 30% and 39%. Two lesions were 40% diameter stenosis, 4 were 50%, and 1 each were 60%, 70%, 75%, 80%, and 90% stenosis.

With subjects classified by presence or absence of new lesions, mean values of major clinical variables are presented in Table 1. Descriptively, compared to subjects who did not develop new lesions, subjects who developed new native lesions were usually younger at study entry, had recently undergone bypass surgery, had lost less weight on-trial, and had increased both systolic and diastolic blood pressure while on-trial. Those who developed new lesions also showed minor changes in total cholesterol and LDL-cholesterol (less than 1% decrease in both), a 2% decrease in non-HDL-cholesterol, a 5% increase in HDL-cholesterol, and a 10% decrease in triglycerides. In comparison, CLAS placebo subjects who did not develop new lesions demonstrated larger decreases in total, LDL, and non-HDL-cholesterol (6%, 7%, and 7%, respectively), no change in HDL-cholesterol, and an 8% decrease in triglycerides. Subjects developing new native lesions also had a lower average baseline value of apolipoprotein B (average 111.1 mg/dL compared to 124.1 mg/dL in subjects not developing new lesions) and demonstrated an 8% increase in this variable while on-trial. Subjects who did not develop new lesions showed no average on-trial change in apolipoprotein B. Table 1 also presents the univariate ORs and 95% CIs for each variable. All variables have been divided by their sample standard deviation (SD) so that the resulting ORs represent the relative risk for a 1 SD increase in that variable.

TABLE 1—Independent Variable Means by Lesion Group

Variables	New Lesions Mean ± SD (n = 18)	No New Lesions Mean ± SD (n = 64)	SD[a]	OR[b]	95% CI
Age at study entry	51.7 ± 5.0	55.2 ± 15.7	4.4	0.5	0.3–0.8
Years since bypass	2.4 ± 1.5	2.9 ± 2.3	2.3	0.7	0.4–1.3
Body weight (lbs)					
Baseline	178.3 ± 16.7	177.7 ± 23.3	21.9	1.0	0.6–1.7
On-trial	178.1 ± 16.3	176.8 ± 25.2	23.4	1.1	0.6–1.8
Difference	0.2 ± 6.1	0.9 ± 5.8	5.9	0.9	0.5–1.5
Diastolic BP (mm Hg)					
Baseline	80.8 ± 9.3	80.3 ± 8.3	8.5	1.1	0.6–1.8
On-trial	83.4 ± 7.3	80.1 ± 7.1	7.3	1.6	0.9–2.9
Difference	−2.6 ± 4.5	0.2 ± 4.2	4.4	0.5	0.3–0.9
Systolic BP (mm Hg)					
Baseline	118.8 ± 11.2	124.7 ± 12.0	12.0	0.6	0.3–1.1
On-trial	121.4 ± 10.2	123.0 ± 11.5	11.2	0.9	0.5–1.5
Difference	−2.7 ± 7.1	1.6 ± 6.3	6.9	0.5	0.3–0.9
Plasma total cholesterol (mmol/L)					
Baseline	6.3 ± 1.0	6.3 ± 0.9	0.9	1.0	0.6–1.6
On-trial	6.2 ± 1.2	5.0 ± 0.8	0.9	1.3	0.8–2.1

Difference	0.0 ± 1.7	−0.1 ± 1.4	1.4	1.1	0.6–1.8

Note. Difference = baseline minus mean ontrial value; CI = confidence interval.
[a]SD = Standard deviation for entire sample (N = 82).
[b]Odds ratio = relative risk per SD change of independent variable (relative to no change).

Independent variables showing univariately significant trends in relative risk for new lesion formation are displayed in more detail in Table 2. To show the trend in relative risk, each variable was categorized into four levels using the sample quartiles, and ORs were estimated for each level relative to the first quartile.

Age at entry into the study was protective for new lesions; thus, older men were less likely to develop new lesions. Dividing the total group of 82 men at the median age (54.5 years), the risk of new lesion development for men above the median was 0.2 times that of men below or at the median age (95% CI = 0.1–0.7). Conversely, the risk for new lesion formation in men younger than 55 years at study entry was 4.8 times that of older men. Inclusion of other significant independent clinical and diet variables[21] did not alter the significance of the influence of age on lesion development.

Changes in both diastolic and systolic blood pressure and total plasma cholesterol from baseline to mean on-trial values were also significant univariate predictors of new lesions (Table 2). Decreases in blood pressure and total plasma cholesterol from baseline to on-trial conferred lower risk for development of new atherosclerotic lesions. Other independent variates, including HDL-, LDL-, and non-HDL-cholesterols, apolipoproteins A-I, B, and C-III, triglycerides, body weight, and years since bypass, were not significantly associated with new lesion formation. Finally, variables indicating whether or not a subject had used platelet-active medications, calcium channel blockers, or other antihypertensive medications were not significantly related to new lesion formation.

To investigate the differential effects of lipids by age, interactions between a dichotomized age variable (dichotomized at the median age at study entry) and plasma lipids measured at baseline and on-trial were included in the logistic regression procedure. Two significant interactions emerged in these analyses. The first interaction was an age-on-trial HDL-cholesterol interaction ($\chi^2 = 3.96$; df = 1; $P = .046$), with the parameter estimate indicating a protective effect for HDL-cholesterol confined to subjects older than 55 years. The interaction between age and on-trial triglycerides was also significant ($\chi^2 = 7.00$; df = 1; $P = .01$) with an increased risk for lesion development due to increased triglyceride level occurring in the older age group. In both cases, the main effect of age remained significant after inclusion of these interactions.

To determine which of the univariately significant variables were independently predictive of new native lesions, a stepwise logistic regression analysis was performed (Table 3). Age at study entry was the first independent variable to enter the model; the risk for development of new native lesions was decreased by a factor of 0.4 for every 4.4 years (ISD) of age. After adjusting for age, the change in systolic blood pressure from baseline to on-trial was also significantly predictive of new lesion formation; each 7 mm Hg decrease in systolic blood pressure was associated with the risk of new lesions being decreased by a factor of 0.5. No other variables were significantly related to lesion development after inclusion of these two variables.

Of the 18 subjects who had developed new lesions, 11 had new lesions in native arteries with related grafts, while 7 had new lesions in native arteries without a related graft. These two subgroups were separately compared to the 64 subjects who did not develop new lesions. Parameter estimates for the final model (age at entry into study and change in systolic blood pressure) did not change from those displayed in Table 3, suggesting that these effects are the same in native arteries with and without related bypass grafts.

Discussion

Our analyses are focused on the appearance of new lesions visible by angiography because these indicate an increase in the extent of raised intrusions into the coronary lumen, the most significant single anatomic predictor of ischemic heart disease (IHD) at autopsy.[25] We are concerned primarily with relationships within the placebo group because new lesions were more common here and because these relationships are more relevant to primary IHD prevention than those among drug-treated subjects. Reduction of new lesions in secondary prevention has merit, but reduction of new lesions in primary prevention could benefit many more individuals and might lead to population-wide control of IHD. We have previously reported reduction of new lesions in secondary prevention in CLAS through aggressive treatment with colestipol plus niacin.[1] This treatment reduced average total plasma cholesterol from 6.36 to 4.65 mmol/L and reduced the relative risk of new lesions by a factor of 0.4 ($P = .03$). We have also reported an analysis of diet records of CLAS placebo subjects relevant to primary prevention that indicated that reduction of new lesions might be accomplished by reducing dietary fat.[21] We now report an additional analysis of risk factors relevant to primary prevention that have significant effects on new lesion formation independent of diet. In CLAS placebo subjects, risk for new lesions was predicted by age, on-trial reduction of total plasma cholesterol, and on-trial reduction of both systolic and diastolic blood pressure. When these four univariate predictors competed in stepwise logistic regression, age and change in systolic blood pressure were found to be significant. The effect of age is significant in analyses that pool drug subjects with placebo.

TABLE 2—Univariately Significant Predictors of New Lesion Formation[a]

	OR	95% CI	*P* trend
Age at entry to study, y			
40 to 52	1.0		.006
>52 to 54.5	0.3	(0.1, 1.1)	
>54.5 to 58	0.1	(0.02,0.6)	
>58	0.1	(0.03,0.8)	
Change in total blood cholesterol (mmol/L)			
≤0	1.0		.040
>0 to 0.2	0.8	(0.2, 2.9)	
>0.2 to 0.6	0.6	(0.2, 2.5)	
>0.6	0.2	(0.1, 1.4)	
Change in diastolic blood pressure (mmHg)			
≤−4	1.0		.022
>−4 to −1	0.4	(0.1, 1.5)	
>−1 to 3	0.3	(0.1, 1.5)	
>3	0.2	(0.04,1.1)	
Change in systolic blood pressure (mmHg)			
≤−3	1.0		.024
>−3 to 1	0.6	(0.2, 2.3)	
>1 to 5	0.4	(0.1, 1.8)	
>5	0.2	(0.04,1.3)	

Note. OR = odds ratio; CI = confidence interval.

[a] Change variables = baseline minus mean on-trial.

TABLE 3—Stepwise Logistic Regression

Variable	OR[a]	95% CI[b]	*P*
Age at study entry	0.4	0.2–0.8	.005
Change in systolic blood pressure	0.5	0.3–0.9	.021

[a] Odds ratio interpreted as change in risk per standard deviation of age or standard deviation change in systolic blood pressure.

[b] CI = confidence interval.

The multivariate stepwise model associated with on-trial change in systolic blood pressure and age indicates that reduction of systolic blood pressure by 10 mm Hg reduced the risk of the new lesion development by 60% in men of median age 54.5 years. It is important to note that the principal antihypertensive agents used in CLAS placebo subjects were propranolol, hydrochlorothiazide, and dyazide, not slow calcium channel antagonists. When variables indicating whether or not a subject had taken calcium channel blockers or other antihypertensive medications were introduced into logistic regression, they were not significantly related to new lesion formation. We conclude that reduction of blood pressure level per se, rather than the agent used to produce the reduction, was the significant influence in CLAS placebo subjects. Thus, modest changes in blood pressure perceptibly altered atherogenesis at the stage of raised lesion development. This finding is compatible with the large body of epidemiologic evidence for long-term effects of blood pressure on population IHD rates.[27,28] Trials of antihypertensive therapy such as the Multiple Risk Factor Intervention Trial[29] may have failed to show reduced IHD rates because benefits from reduced new lesion formation were masked by catastrophic events in existing coronary lesions.

In summary, placebo group data from CLAS indicate that formation of new intrusive coronary lesions is significantly influenced by age and change in blood cholesterol and blood pressure level. The effects of blood pressure and blood cholesterol are compatible with findings from IHD epidemiology and confirm that it is appropriate to reduce these risk factors for primary IHD prevention. Age was observed to have a negative effect, with more young subjects showing new lesion formation. This indicates the need for improved methods to identify young individuals who form new coronary lesions at accelerated rates. □

A Randomized Trial of an Interim Methadone Maintenance Clinic

ABSTRACT

Background. Interim methadone maintenance has been proposed as a method of providing clinically effective services to heroin addicts waiting for treatment in standard comprehensive methadone maintenance programs.

Methods. A clinic that provided initial medical evaluation, methadone medication, and AIDS education, but did not include formal drug abuse counseling or other social support services was established in New York City. A sample of 301 volunteer subjects recruited from the waiting list for treatment in the Beth Israel methadone program were randomly assigned to immediate entry into the interim clinic or a control group.

Results. There were no differences in initial levels of illicit drug use across the experimental and control groups. One-month urinalysis follow-up data showed a significant reduction in heroin use in the experimental group (from 63% positive at intake to 29% positive) with no change in the control group (62% to 60% positive). No significant change was observed in cocaine urinalyses (approximately 70% positive for both groups at intake and follow-up). A higher percentage of the experimental group were in treatment at 16-month follow-up (72% vs 56%).

Conclusions. Limited services interim methadone maintenance can reduce heroin use among persons awaiting entry into comprehensive treatment and increase the percentage entering treatment. (*Am J Public Health*. 1991;81:1185–1191)

Introduction

Expansion of drug abuse treatment programs has been one of the more frequently recommended means for controlling the spread of the human immunodeficiency virus (HIV) and AIDS among intravenous drug users (IVDUs). In the United States, the Presidential Commission on the HIV Epidemic[1] and the National Academy of Sciences[2,3] have both advocated "treatment on demand" (providing immediate voluntary entry into treatment) for IVDUs. The National Institute on Drug Abuse has determined that providing treatment for IVDUs will be its primary strategy for reducing the spread of HIV among drug injectors.[4]

The Food and Drug Administration (FDA) has proposed changing the regulations governing methadone maintenance treatment in the United States to permit interim methadone treatment. The term "interim" refers to the provision of limited services to patients awaiting treatment positions in comprehensive methadone programs. Interim clinics would provide intake physical examinations, education about AIDS, and methadone medication to prevent narcotic withdrawal symptoms and to block the euphoric effects of heroin. The methadone would be dispensed daily by a nurse so that there would be frequent contact between the patient and the medical staff and minimal opportunity for diversion of the medication. Interim clinics would not be required to provide ongoing drug abuse counseling, vocational rehabilitation, or the other social services that are incorporated in current federal regulations governing methadone maintenance treatment and that are integral components of most drug-free programs.

According to their proponents, interim clinics would not replace regular methadone maintenance programs, but would provide limited services to heroin addicts who would otherwise be on waiting lists and receiving no drug abuse treatment. The limited services are expected at least to reduce heroin use and the AIDS risks associated with heroin use. Opponents argue that interim methadone maintenance would not address the multiple social and vocational needs of most heroin addicts, and that implementation of limited service treatment might impede expansion of more comprehensive treatment programs, or, in a time of limited public resources for drug abuse treatment, even replace more comprehensive treatment.[1] (For an extended discussion of the proposed FDA regulations that would have permitted interim methadone maintenance treatment see the transcript of hearings conducted by the Select Committee on Narcotics Abuse and Control of the U.S. House of Representatives, March 23, 1990.)

The intensity of debate notwithstanding, there are relatively few data on the effectiveness of interim methadone clinics. Hong Kong and The Netherlands both have some methadone maintenance pro-

grams that provide few supportive services beyond basic dispensing of the medication. These programs are generally considered effective within those societies,[5,6] but the effectiveness of interim methadone maintenance might be different in the United States, due to cultural differences with respect to drug use and the higher percentage of polydrug use among US heroin addicts. We report here on a random assignment evaluation of an interim methadone clinic in New York City. Subjects receiving interim clinic services were compared to waiting list controls. Change in heroin use was the primary outcome measure utilized; changes in cocaine use and entry into conventional treatment were also examined.

Methods

Interim Clinic Services

The interim clinic was opened in February 1987. It was staffed by a one-quarter-time physician, one full-time registered nurse, one clinic coordinator, one outreach worker, and one full-time research interviewer. The services provided within the clinic included a standard physical examination upon admission and methadone administered by a nurse 5 days per week. Saturday medication and a single take-home dose were provided at another site in the same building. AIDS education, with free distribution of condoms, was also provided at the interim clinic. Urine samples were collected biweekly for toxicologic analyses, which included thin layer chromatography with confirmation by gas chromatography/mass spectrometry performed by Damon Clinical Laboratories of New York.

Results of the urinalysis were known to the treatment staff, but not incorporated into any treatment plan or discussed in formal counseling sessions, as they generally would be in a comprehensive methadone treatment program. Minimal counseling was available on an ad hoc, informal basis, and other supportive service needs could be addressed only by referral to community agencies. The physician could identify medical problems but, except for the most routine of interventions, had to refer patients elsewhere for treatment.

The initial dose of methadone was set by the examining physician based on the examination and drug use history and was typically 20 to 30 mg/day. This initial dose was then increased according to an escalation schedule preset by the physician, generally by 10 mg every third day until a maintenance dosage of approximately 80 mg/day was reached. The nurse was authorized to modify the rate of dose escalation or to stop the escalation process at a stabilization dose other than the scheduled maximum. Dosage adjustment decisions generally reflected subjective perceptions of the patients and instances of missed or vomited medication.

Subjects and Data Collection

Subjects were recruited from the waiting lists of the Beth Israel methadone maintenance program. Separate waiting lists are maintained for the 23 Beth Israel clinics, and there is substantial variation in the time between application for treatment, placement on a waiting list, and admission to one of the regular clinics. At the time of the interim clinic study, the average time spent on a waiting list was approximately 3 months. Participation in the study would be from the time of enrollment until an opening occurred at the clinic to which the subject had originally applied. At that time the subject would be enrolled in the regular clinic and cease participation in the interim clinic study. Participation in the study would neither decrease nor increase the time spent waiting for an opening in a regular clinic.

A written informed consent for participation in the study was obtained from each subject. The project was approved by Beth Israel's Institutional Review Board and the FDA (Investigational New Drug number 28 232). A questionnaire covering demographics, drug use history, AIDS risk behavior, and knowledge of AIDS was administered by a trained interviewer. The subjects were informed that medical and drug use information collected at the interim clinic would not be revealed to the comprehensive clinic to which they would ultimately transfer. Subjects were paid $35 for the completion of intake data collection. A follow-up questionnaire, focusing on drug use since the preceding interview, was administered every 2 weeks.

Residual serum from the blood sample collected as part of the intake examination was stored at −70 °C for later HIV testing. Since the object of the study was to examine the effects of a methadone treatment program that did not include formal counseling, the actual HIV counseling and testing were postponed until completion of the evaluation study. (Relationships between serostatus and drug use behavior will be presented elsewhere.)

After completion of the initial data collection, subjects were assigned randomly to experimental treatment or control conditions. The random assignment was done by administrative staff at a different location. The intake interviewers frequently asked to have individuals placed in the methadone treatment group based on data obtained in the intake interview, but, consistent with the protocol, these requests were not honored. Subjects in the control condition were paid $20 for follow-up interviews. Data were analyzed using the PRODAS system of statistical programs.[7]

Change in Protocol

For the first 3 months after the study inception, there were three experimental conditions: the experimental treatment group immediately received interim clinic treatment as described above and a biweekly follow-up interview; the frequent contact control group received the biweekly follow-up interview, free condoms, and had biweekly urine samples collected; and the minimal contact control group were not reinterviewed until the end of their participation in the study.

Subject recruitment under these conditions was initially rapid, but then slowed dramatically. Discussions with recruited subjects and potential subjects applying for methadone treatment at Beth Israel indicated that the major difficulty was the perception of a low probability (one chance in three) of receiving methadone treatment in the interim clinic study.

In August 1987, the protocol was revised to increase subject recruitment. The minimal contact control group was eliminated from the study, and the time spent in the frequent contact control group was limited to 1 month, after which control subjects were switched into the experimental group and received methadone medication. After this modification, there was no difficulty in recruiting new subjects for random assignment into experimental and control conditions and the 150-person limit on patients receiving methadone in the interim clinic was soon reached. Data from the discontinued minimal contact control group are not included in this report, but are available from the senior author (S.R.Y.).

Data Collection Limitations

One research staff member was designated to conduct baseline and biweekly research interviews for the experimental and control subjects. The outreach worker, who was bilingual (Spanish/English), occasionally assisted in interviewing. It is thus unlikely that the subjects maintained a clear separation between clinic treatment staff and research staff, which may have contributed to underreporting of drug use as presented below.

TABLE 1—Selected Demographic and Drug Use Characteristics for Subjects at Entry Into Study (N = 301)

Average age began IV drug use on regular basis (yr)	19.5		20.2		t=1.02	.31

[a] MMTP = methadone maintenance treatment program.

Given the number of subjects and the severe limitation of clinic space and personnel, some urine collections and interviews were not conducted at the required intervals, especially in the first few months of the study when new intakes and biweekly follow-up interviews for both experimental and control subjects were needed. As the study progressed and the control participants reached their 30th day and were transferred to the experimental treatment group, the total number of study participants stabilized at the maximum of 150 patients receiving methadone, and the rates of missed urines and interviews diminished considerably.

Results

Table 1 shows demographic characteristics and drug use histories for the 301 subjects who were assigned to the experimental and frequent (biweekly) contact control conditions. Ninety-eight percent reported that they had injected drugs at some time in their lives; 92% reported injecting in the month prior to entry into the study, with a mean of over three injections per day. There were no significant differences between groups in demographics or drug use histories. More than half of those who were tested for HIV were seropositive, with a higher percentage seropositive in the control group.

Of the 301 subjects initially enrolled, no follow-up data were obtained from 41 subjects (20 from the experimental group, 21 from the control group). Of these 41 subjects, 32 were lost to contact, 8 were admitted to traditional drug treatment, and 1 was incarcerated before follow-up data could be collected.

Since control subjects were shifted into the experimental treatment after 1 month, primary outcome comparisons between the two groups must be restricted to behavior within that time period. Complete baseline and 1-month follow-up data are available for 169 subjects initially assigned to experimental and frequent contact control groups. The 1-month period was operationally defined as between 15 and 44 days after intake. For subjects with multiple follow-up interviews and urine samples during their participation in the study, the interview and urine sample collected nearest 30 days was used, with the restriction that data from the control subjects reflected only time spent in the control condition. Table 2 presents demographic and drug use history data for these subjects. They do not differ significantly on any of these variables from the total groups assigned to experimental treatment and frequent contact control conditions.

Table 3 presents baseline self-reported drug use and urinalysis results at enrollment for the 169 subjects with complete baseline and follow-up data. There is a general agreement between the self-reports and the urinalysis results. None of the differences between the two groups are statistically significant by chi-square tests.

Table 4 presents self-reported drug use and urinalysis results at the 1-month follow-up. There is clearly substantial underreporting among members of the experimental treatment group. Factors associated with discrepancies between self-reported drug use and urinalysis results will be examined in a separate paper. The drug use analyses presented in this report will be restricted to urinalysis results only. Comparisons of the urinalysis results across experimental treatment and control groups at 1 month using chi-square tests show less heroin use ($\chi^2 = 15.35$, $P < .001$) and more methadone use ($\chi^2 = 52.86$, $P < .001$) in the experimental group. The very small difference in cocaine use was not significant ($\chi^2 = .09$, $P = .7$) between the two groups.

Comparisons from intake to the 1-month time period within each group showed significantly reduced heroin use (63% to 29%, McNemar $\chi^2 = 16.45$, $P < .001$) and significantly increased methadone use in the experimental group (33% to 92%, McNemar $\chi^2 = 36.98$, $P < .001$). The decrease in cocaine use in the experimental treatment group was not significant (from 77% to 66%, McNemar $\chi^2 = 1.33$, $P < .3$). In the control group, neither the heroin nor cocaine use percentages changed significantly, but there was also a trend toward increased (illicit) methadone use (26% to 37%, McNemar $\chi^2 = 3.225$, $P < .10$).

To determine whether the 169 subjects included in Table 4 were a biased sample of all subjects in the study, we examined urinalysis results for 129 subjects originally assigned to the experimental treatment group and 121 subjects originally assigned to the frequent contact group for whom there was at least one follow-up urinalysis result. These represent 87% of all subjects originally assigned to the experimental treatment group and 80% of all subjects originally assigned to

the frequent contact control group. The urine sample collected closest to 30 days in the study was used for this analysis. For the experimental treatment group, the urinalysis at follow-up showed 47 (36%) had used heroin, 99 (77%) had used cocaine, and 117 (91%) had used methadone. For the frequent contact control subjects, 72 (60%) had used heroin, 93 (77%) had used cocaine, and 49 (40%) had used methadone. These results are similar to those reported in Table 4, although the percentage for heroin use in the experimental treatment group and the percentages for cocaine use in both the experimental and frequent contact control groups are modestly but not significantly higher. The difference in heroin metabolites between the experimental treatment group and the frequent contact control group at follow-up is still highly significant (χ^2 = 13.22, P < .001).

In order to further explore possible determinants of heroin use at 1 month, univariate analyses (chi-square tests and *t* tests) on the 169 subjects with complete intake and 1-month follow-up data were performed to determine if demographic characteristics, drug history variables, or cocaine use were associated with heroin use at 1 month. Only use of cocaine at 1 month and assignment to the control group were significantly associated with heroin use at 1 month, as presented in Table 5.

Inspection of the data showed similar relationships between heroin use and cocaine use at 1 month for both the experimental treatment group and the control group. Among the 75 subjects in the experimental treatment group, 25% had evidence of both cocaine and heroin use in their urine sample, 4% had evidence of heroin use only, 43% had evidence of cocaine use only, and 28% had no evidence of either drug (χ^2 = 4.82, P < .05). The relationship was slightly weaker among the 94 subjects in the control group: 46% had evidence of both cocaine and heroin use in their urine sample, 14% had evidence of heroin use only, 24% had evidence of cocaine use only, and 16% had no evidence of either drug (χ^2 = 2.86, P < .09). Because the urinalysis performed was capable of detecting cocaine use only for the previous several days and was capable of detecting heroin use for the previous week, these results probably underestimate concurrent use of both drugs for both groups.

Multiple logistic regression was used to examine whether treatment group status and the presence of cocaine metabolites in the 1-month urine sample were independent predictors and whether interactions between experimental group status and demographic or behavioral variables were associated with heroin use at 1 month. Such interaction effects would indicate subjects for whom interim clinic treatment might be particularly effective or not effective in reducing heroin use. The final regression equation is presented in Table 5. Both treatment group status and cocaine use at 1 month were independent predictors of heroin use at 1 month, and none of the possible interactions between treatment group and the demographic and behavioral variables were significant.

A final aspect of the experimental treatment versus control group comparisons was to examine the numbers of subjects who had entered conventional drug treatment programs at the end of data collection in June 1988, i.e., 16 months after the program began. As shown in Table 6, of the 301 subjects originally enrolled in the experimental treatment and the frequent contact control groups, 107 (72%) of those in the experimental group had been enrolled in conventional drug treatment by this data vs 85 (56%) of the controls. This difference for entering conventional treatment was statistically significant ($\chi^2 = 8.23, P < .005$).

Discussion

This study was based on the hypothesis that participation in a rapid intake, limited service methadone maintenance treatment program would reduce illicit drug use and AIDS risk behaviors among persons with a history of heroin addiction. The study attracted a group of subjects with long histories of illicit narcotic use; the great majority had previous drug abuse treatment experience. These subjects are similar in their demographic characteristics to others admitted to the Beth Israel Methadone Maintenance Treatment Program during the same time period and to other persons admitted to New York State–funded methadone treatment programs in New York City during the same time period.[8] The rate of recent cocaine use was high among these subjects, with over 60% showing cocaine metabolites in the urine specimen taken at study entry.

Random assignment studies have been difficult to conduct in the drug abuse treatment field because of difficulties in recruiting subjects into and keeping them in treatment conditions that they do not want to be in. This study experienced similar difficulties when subjects had only a one in three chance of receiving methadone treatment. After the change in the protocol, the random assignment to either immediate limited service methadone treatment or a time-limited frequent contact control group appears to have been successful. There were few difficulties in recruiting subjects with this change and there was only one variable (HIV status) on which the two groups differed. Since the actual testing of the residual serum for HIV antibody was not done until after random assignment and data collection for this study had been completed, there is no way in which the test results could have influenced the randomization, and we assume that this difference between the experimental treatment and control groups was a random effect.

Ethical considerations required that only volunteers be used in this experimental study. Thus it is not possible to ascertain how these subjects might have differed from persons on the waiting list who chose not to participate and simply waited until a regular treatment position was available. Subject recruitment varied with the perceived likelihood of receiving methadone treatment in the interim clinic, suggesting that large numbers of persons on waiting lists would apply for interim treatment if they were certain that they would receive such treatment.

Because of the substantial discrepancies in self-reported drug use at follow-up, only urinalysis results could be used as a measure of follow-up drug use. Such discrepancies are common when clients in treatment suspect that drug use will lead to some form of negative sanctions.[9] Restricting the comparisons to the urinalysis data prevented assessment of the AIDS risk associated with drug injection, but given the long histories of drug injection among these subjects, it is a reasonably safe assumption that a very high percentage of both heroin and cocaine use was by injection.

Based on the urinalysis results, participation in the interim clinic was associated with a substantial decrease in heroin use. Heroin use at 1 month was reduced by approximately half for the experimental treatment group compared to either heroin use at intake or heroin use among the control group at 1 month. Immediate intake into the limited services methadone treatment was also associated with a higher percentage of subjects being enrolled in comprehensive drug treatment. It is not surprising that receiving even limited interim services would facilitate entry into conventional treatment compared to being on a waiting list. Little is known about why many drug users apply for treatment and are placed on waiting lists but do not enter treatment, but at the least they must be considered missed opportunities for reducing illicit drug use and preventing HIV infection.

The regression analysis for possible interactions between experimental group status and other demographic and behav-

TABLE 5—Potential Predictors of Heroin in Urine Sample at the 1-Month Follow-up (n = 169)

Average age began IV drug use (yrs) on regular basis	20.4		t=.91	.36

Note. In the final logistic regression equation: beta for the intercept = −0.29, with a χ^2 of 0.78, p = .3774; beta for group status = −1.30, with a χ^2 of 14.89, P = .0001; beta for cocaine in the urine = .99, with a χ^2 of 7.11, P = .008. Variables were dummy coded to 0/1. For group, a value of 1 indicates that the patient was in the treatment group. For presence/absence of drugs, a 1 indicates that the drug was present in the urine at 30 days.

[a] MMTP = methadone maintenance treatment program.

Death	0		2	(1)

ioral characteristics of the subjects did not produce any significant findings. Thus, the present data do not provide evidence for what types of subjects would do comparatively better or worse in interim methadone treatment. Heroin use was more common among interim treatment subjects using cocaine than those not using cocaine. Indeed, it was rare to find a treatment group subject who had evidence of heroin use but not cocaine use in the follow-up urine sample despite the greater time sensitivity for detecting heroin use. Subjects using cocaine may have used heroin simultaneously in "speedball" injections, which produce a drug effect that many users consider preferable to either drug taken alone. Cocaine users might also have taken heroin as self-medication to reduce the dysphoria following cocaine runs. Screening cocaine users out of interim methadone treatment would probably lead to greater reductions in heroin use during treatment, but would not solve the problem of what to do with the large group using both drugs.

The National Academy of Sciences[2,3] and the Presidential Commission on the HIV Epidemic[1] have recommended large-scale expansion of drug treatment in the United States as a method of reducing both illicit drug use and new HIV infections. Even if a financial commitment were made to provide large-scale expansion, it would still take a period of years for new sites to be found and for staff to be hired and trained. During this multi-year process, interim forms of treatment could be of substantial benefit as drug users waited for openings in conventional treatment. The present study did not compare interim treatment to conventional treatment, and we would object to using these findings as a rationale for substituting limited interim services for conventional treatment. We do believe, however, that these findings strongly support providing interim services rather than leaving drug users on waiting lists for conventional treatment. ☐

The Environmental Dental Association Raises Ecological Questions as Consumer Reports Purports Mercury/Silver Fillings "Safe"

The May 1991 issue of *Consumer Reports* notes that each year up to 100 million silver-colored [amalgam] fillings are used to restore decayed teeth. The article reports that almost half of each filling is mercury. The Environmental Dental Association (EDA), a San Diego–based organization consisting of nearly 700 practitioners, maintains that the dental industry has overlooked the environmental issues associated with mercury use.

Over 100 tons of mercury are used per year in the dental industry in the United States alone. Mercury, a known poison, is more toxic than lead or arsenic. Invariably, unused amalgam material and old fillings containing mercury wind up in the hands of unregulated scrap metal dealers or in our landfills. An alarming portion of the silver/mercury filling material goes directly down the drain from dental offices, polluting our lakes, rivers, and other bodies of water. The EDA is currently initiating steps to improve on-site water filtration systems in dental offices, which would prevent further mercury contamination of water supplies.

According to the San Diego County Office of Hazardous Waste Management, the determination of hazardous waste status of dental amalgam is incumbent upon the dentist. Therefore, disposal of dental amalgam is essentially unmonitored. A spokesperson for that department stated that they have had a marked increase in calls concerning this issue, which is likely to result in stricter controls in the future.

Mike Cressler, director of Quicksilver Recycling, one of California's few treatment facilities licensed to accept mercury, recently advised the EDA that the amount of environmental contamination from dental mercury residue is significant. He expressed concern over the lack of general awareness on the part of the dental profession regarding the hazardous nature of dental waste, particularly dental amalgam. Cressler emphasized that dentists need to become more environmentally aware. He projects that the increased incidences of health and environmental liability for dentists who do not comply with environmentally-responsible practices, will likely invoke changes in the industry.

The EDA is also concerned about hazardous indoor air quality within dental offices, posing yet another risk to dental personnel who breath mercury vapor on a regular basis. The Occupational Safety and Health Administration (OSHA) estimates that 10% of all dental offices are severely mercury-contaminated. Most have adequate decontamination systems and fail to enforce the wearing of protective gear.

An FDA advisory committee met on March 15 to evaluate the use of mercury in dentistry. Although there was insufficient evidence to warrant a position that silver/mercury fillings are either safe or unsafe, two leading toxicologists testified that the issue was of legitimate concern. Research protocols to investigate health effects are currently being developed.

According to transcripts from the FDA advisory meeting, one of the world's leading authorities on mercury toxicity, Lars Friber, MD, PhD, said that "dental amalgam, from the strictly toxicological point of view, is an unsuitable dental filling material . . . steps should be taken to use, as far as possible, other material than amalgam." Contrastly, *Consumer Reports* concludes that "all risks have to be measured against the alternatives . . . amalgam fillings are still your best bet."

Although the heated debate rages on, the EDA contends that consumers of dentistry should be informed about the nature of the filling materials used and should be advised of all available options. *Consumer Reports* pointed out that the American Dental Association (ADA) opposes any informed-consent laws requiring dentists to inform patients of the possible hazards of mercury fillings and opposes discussion of alternatives.

According to the article published in *Consumer Reports*, "The question in the amalgam debate is whether the minute amount of mercury vapor thought to emanate from fillings has any health effect at all." EDA president, Joyal W. Taylor, DDS, responded to the comment as follows: "As long as this questions remains unanswered, the public deserves the right to know and the right to choose for themselves. Furthermore, we will continue to advocate environmentally responsibly dentistry."

The EDA provides scientific research data, referrals to over 700 mercury-free dentists and doctors throughout the United States and as a public service offers free information packets. The toll-free number for the EDA is 1-800-388-8124.

Aging and the Fitness of Fire Fighters: The Complex Issues Involved in Abolishing Mandatory Retirement Ages

ABSTRACT

This study presents an assessment of the cardiorespiratory health and physical fitness of fire fighters of different ages with the aim of addressing several questions currently being debated on a national level. These include how fire fighters differ across age groups in their health and physical fitness, and what would be the impact on the existing work force of implementing minimum fitness standards as an alternative to mandatory retirement ages.

Fire fighters aged 20-65 years were found to be similar in their cardiorespiratory health and physical fitness to the sedentary segment of the general population of the same age. Particularly worrisome, however, is the low maximal aerobic capacity (31, 28, 26 ml/kg/min), high percent body fat (26, 29, 30), and high resting blood pressure (136/86, 140/90, 143/93 mm Hg) observed in the 40-45-, 50-55-, and 60-65-year-old fire fighters, respectively. In fact, 66%, 83%, and 93% of the fire fighters in these three age groups, respectively, fall below the lowest published recommendations for maximal aerobic capacity in this profession.

These data underscore the need to establish minimum health and physical performance standards for fire fighters and demonstrate the profound impact such minimum standards will have on the existing work force. (*Am J Public Health*. 1991;81:1192–1194)

Introduction

The feasibility of abolishing mandatory retirement ages in public safety occupations is being studied under US congressional mandate. One suggestion has been to replace mandatory retirement ages with minimum standards for health and physical fitness.[1] Before serious discussion regarding developing and implementing standards can begin, the impact of those standards on the current work force must be known. Therefore, we conducted a descriptive case study of a large municipal fire department (approximately 5000 uniformed personnel) in order to (1) describe differences across age groups in selected measures of physical fitness and health using a cross-sectional design and (2) develop hypotheses on the impact of implementing physical performance standards on the existing work force

Methods

Subjects were recruited from a randomized listing of all uniformed full-time fire fighters from a large municipal fire department. The 150 subjects were divided by age into five groups of 30 each: aged 20 to 25, 30 to 35, 40 to 45, 50 to 55, and 60 to 65 years. No more than 40 individuals in each age group had to be contacted in order to obtain the 150 volunteers.

Cardiovascular status was determined from a graded exercise test employing a modified Balke treadmill protocol. ECG, blood pressure, and heart rate were taken at rest; at the end of each stage of exercise; and at 1, 3, and 5 minutes during recovery. Expired gases were collected during the last 1 to 4 minutes prior to volitional fatigue or symptom-limited test termination. Maximal oxygen uptake (VO2max) was measured using an open circuit system as described elsewhere.[2]

Pulmonary function testing was performed using a Collins Survey Spirometer. From a forced vital capacity (FVC) maneuver, forced expiratory volume at 1 second (FEV1) and forced expiratory flow rate between 25% and 75% of FVC (FEF25–75) were calculated using standard procedures.

Percentage of body fat was estimated based upon skinfold thickness of the abdomen, chest, and thigh as measured with a Lange skinfold caliper. The average of three measurements at each site was used in a regression equation to predict percentage of body fat.[3]

Measurements of grip strength, standing long-jump, and situps were made for inclusion with selected cardiovascular and anthropometric variables in the composite fitness evaluation system developed by Davis et al.[4]

Analysis of variance using a post hoc Scheffe test was employed to determine any statistically significant ($P < .05$) differences between the age groups.

Results

Aerobic capacity significantly decreased from the 20- to 25-year-old group (47.7 ml/kg/min) to the 30- to 35-year-old group (37.9 ml/kg/min) and from the 30- to

% Who exercise more than twice per week	60	40	17	10	33

Note: BTPS = body temperature and pressure, saturated; FEV1 = forced expiratory volume at 1 second; FEF25–75 (l/s) = forced expiratory flow rate between 25% and 75% of forced vital capacity.
[a] n = 30 for each group.
[b] Data are expressed as mean ± standard deviation.

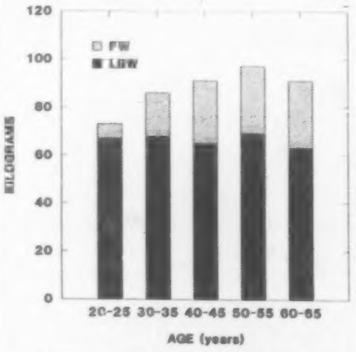

FIGURE 2—Lean body weight (LBW) and fat weight (FW) as a portion of total body weight in fire fighters across age groups.

35-year-old group to the 40- to 45-year-old group (31.5 ml/kg/min) (Figure 1). Given these values for VO2max, Table 1 indicates the percentage of fire fighters in each of the five age groups who would pass various published recommendations for VO2max in fire fighters.

Resting data on blood pressure and pulmonary function are presented for each of the age groups in Table 2. Both systolic and diastolic pressures are significantly higher in the 50- to 55-year-olds and 60- to 65-year-olds than in the 20- to 25-year-olds. FVC was significantly less in the 60- to 65-year-olds than in the 20- to 25-year-old group. Also presented in Table 2 are self-reported data on smoking history and physical activity.

Figure 2 presents lean body weight and fat weight across age groups. Percentage of fat increased significantly from ages 20 to 25 years (8.3%) to 30 to 35 years (19.4%) and again from 30 to 35 years to 40 to 45 years (27.2%).

Table 3 indicates the percentage of fire fighters in each age group exceeding certain clinical criteria. Fire fighters with over 25% body fat are considered to be moderately obese.[5] Individuals with a resting diastolic pressure (DBP) between 90 and 114 mm Hg or a systolic pressure (SBP) greater than 140 mm Hg are considered to the borderline to moderately hypertensive[6] and are categorized as such in Table 3. The percentage of fire fighters in each age group manifesting positive stress tests according to criteria established by the American College of Sports Medicine[7] are listed in Table 3. Exercise hypertension (SBP > 250 or DBP > 120) was the most frequently observed problem in fire fighters aged 40 to 55. In con-

TABLE 3—Percentage of Fire Fighters in Each Age Group Exceeding Selected Clinical Criteria

	Age Groups[a]				
Criteria	20–25	30–35	40–45	50–55	60–65
> 25% Body Fat	0	27	60	83	77
Borderline to moderate hypertension	20	33	53	70	73
Positive exercise stress test	0	0	7	10	40
Mild to moderate pulmonary impairment	10	13	30	23	53

[a] n = 30 for each group

trast, 10 of the 12 positive stress test results in the 60- to 65-year-old age group were due to ECG abnormalities. The average VO2max of the fire fighters with positive stress tests was 24.5 ml/kg/min. Individuals with either an FEV1/FVC of less than .74 or an FVC less than 79% of predicted[8] are considered to have mild to moderate pulmonary impairment[9] and are also presented in Table 3.

A test battery for assessing the overall physical fitness of fire fighters, which includes measures of strength, cardiovascular status, and pulmonary function and has been shown to be predictive of performance time on a standardized fire suppression test,[4] was also used. According to this rating system, 38% of fire fighters aged 40 to 45, 60% aged 50 to 55, and 96% aged 60 to 65 would be considered poor in their overall fitness for fire fighting.

When fire fighters in each age group were divided into those who reported exercising more than twice a week and those exercising less than twice a week, no significant differences in VO2max, percentage of body fat, or FVC were observed.

Discussion

This case study of a large metropolitan fire department illustrates the complexity of the mandatory retirement age issue faced by municipalities. These data suggest that substantial age-associated declines do occur in the health and physical fitness of fire fighters, although these declines are not necessarily age-dependent. Although fitness standards have been advocated as an alternative to mandatory retirement ages, the data presented here demonstrate that using published recommendations as standards[2,10,13] for the aerobic fitness of fire fighters would have an "adverse impact"[14] on a large segment of the existing work force. Given the existing legal controversies pertaining to adverse impact, a municipality would have to present considerable justification for any proposed standard, which would involve costly research and litigation.[15,16] Lowering standards to avoid adverse impact is legitimate only if public safety is not compromised. Our data suggest that any consideration of a shift in national policy away from mandatory retirement ages should be accompanied by an in-depth examination of the feasibility of developing and implementing medical and fitness standards at the municipal level, and clarification of the controversial issue of whether fitness standards that have adverse impact on certain protected groups are necessary to maintain public safety. ☐

Malnutrition in Elderly Ambulatory Medical Patients

Aaron Manson, MD, and Steven Shea, MD

ABSTRACT

Elderly ambulatory persons may be especially susceptible to malnutrition, particularly those who are poor and socially isolated or have comorbid chronic medical diseases. We found that 98 of 2,986 persons aged 60 years or older attending a hospital-based medical practice between 1979 and 1989 weighed less than 45.4 kg (100 lbs). All but 1 of these subjects met criteria for malnutrition as judged against age-specific norms for weight. Thus the prevalence of malnutrition in this sample was 3.25% (95% CI 2.61, 3.89%). Interviews and physical examinations of a subsample (n = 16) revealed that all 16 subjects either met anthropometric-based criteria for malnutrition or were being treated for malnutrition. Of the 98 subjects who weighed less than 45.4 kg, 62 (63.3%; 95% CI 53.8, 72.8%) had comorbid conditions that could have contributed to malnutrition. Physicians did not record a diagnosis of malnutrition or weight loss in 47.9% of subjects (95% CI 38.0, 57.8%) and did not prescribe a nutrition supplement for 76.5% of subjects (95% CI 68.1, 84.9%). Subjects treated with nutrition supplement were more likely to have cancer. These findings suggest that malnutrition, both with and without concomitant major comorbid disease, is relatively frequent among elderly ambulatory patients and that a specific nutritional diagnosis is not made in many cases. We suggest that weight under 45.4 kg in an elderly person is a useful criterion for identifying elderly patients at nutritional risk. (*Am J Public Health.* 1991;81:1195–1197)

Introduction

In 1968 Jean Mayer testified before Congress that as many as 10% of Americans were malnourished due to poverty.[1] During the ensuing decade, government programs reduced malnutrition, but more recently funding for these programs has diminished.[2] The two largest nutritional surveys in the United States, the Ten-State Nutrition Survey[3] and the National Health and Nutrition Examination Surveys (NHANES I and II),[4–6] collected comprehensive data but were conducted in the 1970s, and neither study estimated the prevalence of malnutrition in the elderly. Other studies of malnutrition or weight loss among the elderly are anecdotal, describe small numbers, include hospitalized patients, or do not estimate the prevalence of malnutrition in the populations studied.[7–24] We therefore studied the prevalence of malnutrition among elderly ambulatory patients.

Methods

The study population consisted of outpatients aged 60 years or older, who were receiving care in the medical faculty practice at Columbia-Presbyterian Medical Center, and whose recorded weights in the practice database were 45.4 kg (100 lbs) or less on at least two office visits during the period from 1979 to 1989. Patients were routinely weighed on a balance scale at most visits. In 1989, there were 8,956 patient records in the database; of these 2,987 (33.3%) referred to patients who were age-eligible; one age-eligible patient did not have a recorded weight in the database. Hospital charts of 124 of the 128 age- and weight-eligible patients were obtained, and these patients' weight of 45.4 kg or less on at least two visits in 98 of these 124 patients was confirmed (Table 1).

We reviewed the medical records of these 98 patients using standardized data forms. The diagnoses of malnutrition or weight loss were considered to have been recorded if there was explicit mention in the chart subsequent to the index visit. Treatment of weight loss or malnutrition was considered to have been provided if chart notes recorded the prescription of liquid nutrition supplement. Alcoholism, cancer, severe chronic pulmonary disease, congestive heart failure, dementia, depression, or stroke were noted as comorbid conditions that could contribute to malnutrition.

We further defined nutritional status on the basis of two sets of age- and sex-specific norms, NHANES[25] and the Ten-State Nutrition Survey.[3] Subjects were considered severely malnourished if measurements of weight for height[25] or weight[3] were below the fifth percentile according to these norms. Subjects were considered moderately malnourished if these measurements were between the fifth and fifteenth percentiles.

Results

Laboratory findings in the 98 subjects were consistent with although not specific for malnutrition (Table 1). Of the 48 subjects with recorded heights and weights, 28 (58.3%) were severely malnourished, and 15 (31.3%) were moderately malnourished as measured against the norms from NHANES. All five of the remaining subjects, who could not be classified because their heights were below the minimum height in these distributions, either were taking nutrition supplements or had a diagnosis of malnutrition in the medical record. Measured against norms based on weight alone[3] 2 subjects more than 85 years old could not be classified, 48 (49.0%) were severely malnourished, 42 (42.9%) were moderately malnourished, and 6 (6.1%) were above the 15th percentile. Of the 6 subjects above the 15th percentile, 4 were described as malnourished

Basic Characteristics	Subjects with Diagnosis of Malnutrition or Weight Loss (n = 51) Mean SD	Subjects with No Nutritional Diagnosis (n = 47) Mean SD
Age (years)	75.6 ± 9.4	74.7 ± 10.4
Follow-up time (months)	29.9 ± 27.4	36.5 ± 37.0
Weight (kg)[a]	40.8 ± 4.0	41.1 ± 3.9
Height (cm)	153.3 ± 11.2	157.8 ± 8.2
Albumin (mg/dl)[b]	3.97 ± 0.42	4.04 ± 0.51
Hemoglobin (mg/dl)[c]	12.2 ± 1.6	12.4 ± 2.0
Absolute lymphocyte count[d] (cells/microliter)	1,767 ± 816	1,519 ± 690
Number (percent) men	4 (7.8%)	1 (2.1%)
Comorbid Disease[e]	**Subjects (Percent) with Diagnosis Malnutrition or Weight Loss (n = 51)**	**Subjects (Percent) with No Nutritional Diagnosis (n = 47)**
Alcoholism	5 (9.8%)	3 (6.4%)
Cancer	11 (21.6%)	4 (8.5%)
Chronic pulmonary disease	8 (15.7%)	15 (31.9%)
Depression	10 (19.6%)	9 (19.1%)
Congestive heart failure	9 (17.6%)	11 (23.4%)
Dementia	9 (17.6%)	5 (10.6%)
Stroke	3 (5.9%)	5 (10.6%)

[a] Height was available for 48 subjects.
[b] Serum albumin was available for 80 subjects.
[c] Hemoglobin was available for 77 subjects.
[d] Absolute lymphocyte count was available for 60 subjects.
[e] Sixty-two subjects had one or more comorbid conditions; 28 subjects had more than one.

in the medical record, and a fifth subject met criteria for malnutrition as measured against norms of weight for height.[25] Both extremely elderly subjects were described as malnourished in the medical record. Thus the false positive rate in classifying these 98 subjects using weight alone was 1% or less. We therefore estimated the prevalence of malnutrition among subjects over the age of 60 years in this medical practice as 97 of 2,986 (3.25%; 95% CI 2.61, 3.89%).

The diagnosis of malnutrition was recorded in the charts of 23 subjects (23.5%), and the diagnosis of weight loss was recorded in 28 additional subjects (28.6%, Table 2). Twenty-three subjects (23.5%) were treated with calorie supplement (Table 3). Thus 47 of 98 subjects (47.9%; 95% CI 38.0, 57.8%) had no recorded diagnosis of malnutrition or weight loss, and 75 (76.5%; 95% CI 68.1, 84.9%) were not treated with calorie supplement.

Comorbid conditions that could have contributed to malnutrition were present in 62 subjects (63.3%; 95% CI 53.8, 72.8%, Table 2). Presence of a comorbid condition was not significantly associated with a recorded diagnosis of malnutrition or weight loss; however, such subjects were more likely to have cancer (odds ratio = 2.96; 95% CI 0.87, 10.04).

A substudy (N = 16) of subjects who made scheduled visits to the practice between July 1989 and February 1990 found that the observed weight was 45.4 kg or less in all subjects and that the mean observed weight differed from that in the chart by less than 1%. Using norms for bone-free upper arm muscle area based on triceps skinfold and mid-arm circumference measurements,[25] we found 11 subjects to be below the fifteenth percentile. Of the remaining 5, 4 had a recorded diagnosis of malnutrition or were taking nutrition supplement. The remaining subject met criteria for malnutrition according to norms for weight[3] and weight for height.[25] Thus, all 16 substudy subjects either met anthropometric criteria for malnutrition or were being treated for malnutrition, including 7 subjects with no recorded nutritional diagnosis.

Discussion

This study found that 3.25% of ambulatory elderly patients in a medical practice had evidence of malnutrition, that weight of 45.4 kg (100 lbs) or less is a useful screening criterion for malnutrition, and that the diagnosis of malnutrition was noted in only 52.1% of the 98 malnourished subjects. Of the 98 subjects, 62 (63.3%) had an underlying disease that probably contributed to malnutrition, but more than a third did not; this suggests that malnutrition among the elderly is often present in the absence of major comorbid illness.

It is likely that our method underestimated the prevalence of malnutrition. A weight of 45.4 kg may be too low to identify some malnourished men with larger frames. Thus, only 5 subjects in this series were male.

Although data were collected retrospectively, it is unlikely that information regarding other diagnoses was incomplete since there were computer-based lists of medical diagnoses for all subjects, and the mean observation time in the medical record was 33 months. Weights recorded in the chart were measured during routine care; however, weights measured in the validation substudy corroborated those in the chart.

Although their findings are not conclusive, several longitudinal studies have found that extreme leanness is associated with adverse medical outcomes.[26,27] Al-

[b]Fisher's Exact Test was used to determine statistical significance.
*P = .002. **P = .003.

though the prognostic significance of a weight of 45.4 kg or less (100 lbs) in the elderly is not known, our data indicate that this easily remembered indicator is a useful screening criterion for malnutrition in the elderly and can be used to define the prevalence of this condition.[28] ☐

Acknowledgments

We wish to thank Dr. Haydee Rondon for help with interviewing and examining patients, Dr. Robert Sciacca for help in performing statistical analysis, and the physicians of the Associates in Internal Medicine for providing patients for this study.

Suicides among Older United States Residents: Epidemiologic Characteristics and Trends

Patrick J. Meehan, MD, Linda E. Saltzman, PhD, and Richard W. Sattin, MD

ABSTRACT

Suicide rates for elderly US residents decreased between 1950 and 1980, but have increased recently. We analyzed suicide mortality trends using national mortality data for the period 1980 through 1986. Suicide rates during this period increased for each 5-year age group over age 65. Elderly White males have the highest suicide rates and experienced a rate increase of 23%. The rate for Black males rose by 42%. Divorced males have the highest age-adjusted sex- and marital status-specific rates, and experienced a rate increase of 38% over the 7-year period. Suicide rates among older US residents vary by region of the country and are highest in the West. Rates increased in all regions except the Northeast. Firearms are the most common method of suicide in the elderly, and firearm use increased during this period from 60% to 66% of all suicides. Given the recent increase in suicide rates for the elderly and the magnitude of the problem in this age group, it is again important to direct our attention to the problem of suicide in the elderly and recognize the need for effective prevention strategies. (*Am J Public Health.* 1991;81:1198–1200)

Introduction

Suicide rates for elderly US residents decreased between 1950 and 1980,[1] but have increased recently.[2] Previous studies of suicide among persons of all ages have identified high risk groups including whites, males, widowed or divorced persons, and residents of the western United States.[1,3,4] In this article we examine recent trends in suicide rates for elderly US residents, with an analysis of risk groups and methods used in suicide.

Methods

Data on suicide deaths for the years 1980 through 1986 are from annual mortality data tapes compiled by the National Center for Health Statistics (NCHS), Centers for Disease Control. Suicides analyzed in this article are deaths among persons over age 65 with external cause-of-death codes E950–E959, according to the International Classification of Diseases, Ninth Revision (ICD-9).

Population data used in the calculation of rates by age, sex, and race are from annual computer data tapes produced by the US Bureau of the Census. Marital status-specific and region-specific rates were calculated using population estimates from Bureau of the Census publications.[5,6] Marital status-specific rates were age-adjusted by the direct method (10-year age groups), using the 1980 population as the reference. Because of the small numbers of suicides among other racial groups, we limited our analysis of race-specific rates to the Black and White races.

Results

From 1980 through 1986, 36 789 suicides were reported among US residents over age 65 years, and crude annual suicide rates increased for this age group by 21% (from 17.8 to 21.5 per 100 000). Rate increases ranged from 9% (from 16.2 to 17.7 per 100 000) for the 65- through 69-year age group to 38% (from 18.0 to 24.8 per 100 000) for the 80- through 84-year age group (Table 1). During this period, men accounted for 80% of the suicides among persons over age 65, and rates for men increased for each 5-year age group over age 65.

White males had the highest race- and sex-specific suicide rates for persons over age 65 years (Table 2), and from 1980 to 1986 their rate increased 23% (from 37.2 to 45.6 per 100 000). Suicide rates for Black men increased 42% (from 11.4 to 16.2 per 100 000), and the suicide rates for White women increased 17% (from 6.4 to 7.5 per 100 000).

The 1986 suicide rate for divorced males over age 65 was 3.2 times the rate for married men and 18.9 times the rate for married women (Table 3). From 1980 to 1986, the rate for divorced men increased 38% (from 79.5 to 109.7 per 100 000). Rates for women increased, regardless of the marital status category. However, because the numbers are small, the rates fluctuate more.

In 1986, the western United States had the highest suicide rate for persons over age 65 (29.5 per 100 000), the Northeast had the lowest rate (13.6 per 100 000), and the southern and northcentral regions had intermediate rates (23.7 and 20.2 per 100 000, respectively). From 1980 to 1986, the suicide rate decreased slightly in the Northeast, whereas rates increased in the northcentral (22%), western (23%), and southern (29%) regions.

From 1980 to 1986 firearms were the most common method of suicide for both men and women over age 65 years (Figure 1). Over the 7 years, 73% of older men and 29% of older women committed suicide with firearms. Firearm use increased from

60% of all over-65 suicides in 1980 to 66% in 1986 for both sexes combined.

Discussion

Suicide is the third leading cause of deaths from injury among older US residents, following deaths from falls and from motor vehicle crashes.[2] From 1980 through 1986, suicide rates increased for each 5-year age group over age 65; the only other age groups that experienced a rate increase of at least 5% over this period were the 60- through 64-year age group (10%) and the 15- through 19-year age group (20%) (NCHS Detailed Mortality Tapes 1980–1986).

Although the demographic groups at high risk for suicide among the elderly are similar to those for all ages combined,[1,3,4] differences in suicide rates between demographic subgroups have become more pronounced. For example, the rate ratio between men and women in the >85 age group increased from 9.2 to 13, and the rate ratio for the western region compared with the northeast region increased from 1.6 to 2.2. It is noteworthy, however, that from 1980 to 1986 the rate ratio for Whites over age 65 compared with Blacks narrowed, due to the larger increase in suicide rates among Black men.

In 1986, 66% of suicides among the elderly were committed with a firearm, compared with 57% among persons under age 65. Methods of suicide differ more between men and women over age 65 than for other age groups. In 1986, 75% of male victims over age 65 died of gunshot wounds, compared with 61% of male victims under age 65. During the same year, 31% of female victims over age 65 died of gunshot wounds, compared with 41% under age 65 (NCHS Detailed Mortality Tapes 1986). The use of drugs and poisons is a common method of suicide for older women. Not only do methods of suicide have important implications for the care of acutely suicidal persons, but the availability of specific methods as risk factors for suicide merits further study.

Possible limitations of our data should be discussed. Underreporting has been suggested to be a major source of error in the determination of suicide rates.[4,7] Although the precise extent to which deaths are underreported as suicides is unknown, it is probably a small proportion and should not affect the analysis of trends in suicide rates.[8,9] The denominator used in the calculation of marital status-specific rates is derived from the current population survey, and excludes institutionalized persons. Other rates were calculated using census data and intercensal estimates of the resident US population. Although this methodological difference may affect actual rates, any effect on trends in age-adjusted rates should be minimal.

Known risk factors for suicide that may contribute to high rates and to an increase in rates for the elderly include depression, alcoholism, and chronic illness.[10] Although overall rates of depression may be increasing in the United States,[11] this increase would have to be occurring disproportionately among the elderly to explain the prominent and largely isolated increase in suicide rates for this group. We are not aware of such evidence. Alcohol abuse is less prevalent among the elderly than in younger age groups.[12] It is possible, however, that more people with alcohol-related illnesses are living to an older age, resulting in an increase in the prevalence of alcoholism among persons over age 65 and therefore more at-risk people in this age group. nally, advances in medical care are helping to prolong the lives of persons with chronic illnesses. This could result in higher suicide rates for the elderly, because suicide risk may be higher among chronically ill persons.[13]

Several recommendations can be made based on our findings. We need to consider how current approaches to suicide prevention can better reflect the special circumstances of older persons. Crisis services, for example, may have the greatest impact on the prevention of youth suicide, which may be more impulsive in nature.[14] For older adults, however, addressing the increasingly prevalent problem of social isolation,[15] perhaps reflected in the high suicide rates among divorced persons, may be a more effective prevention strategy. Studies that address the role of economic factors in the precipitation of suicide are needed, as are analytic studies to evaluate, on the individual level, the relationship between correlates of social disruption, such as divorce or geographic migration, and the risk of suicide. Finally, health providers should be increasingly aware of the potential for suicide among the elderly, particularly among those at highest risk, such as divorced older men and Black men. ☐

Development and Validation of a Simple Device to Estimate Birthweight and Screen for Low Birthweight in Developing Countries

Nikorn Dusitsin, MD, MS, Sumana Chompootaweep, MD, MS, Piyalamporn Poomsuwan, MS, Kanchana Dusitsin, MD, Prasertsri Sentrakul, MD, MS, and Pisake Lumbiganond, MD, MS

ABSTRACT

Low birthweight (<2500 g) is the major factor associated with the death of infants within the first 4 weeks of life. The mean birthweight of newborn babies of a certain geographic area reflects the quality of maternal and child health care service as well as the degree of socioeconomic development of that particular region. Hence, birthweight is being used increasingly as an indicator for health and socioeconomic planning. However, in a developing country such as Thailand, two-fifths of the babies are delivered at home and are not weighed because scales are not available. To solve this problem in rural areas, a circular nomographic chart was developed with which the birthweight can be computed from a newborn baby's chest and mid-arm circumferences. Preliminary trials comparing these charts with standard baby scales showed a high degree of accuracy with sufficient sensitivity and specificity. (*Am J Public Health*. 1991;81:1201–1205)

Introduction

Low-birthweight (<2500 g) is the major factor associated with the death of infants within the first 4 weeks of life. The mean birthweight of newborn babies of a certain geographic area may reflect the quality of maternal and child health care service as well as the degree of socioeconomic development of that particular region.[1–4] However, in a developing country such as Thailand, two fifths of the babies are delivered outside hospitals and are not weighed because scales are not available.[5] Anthropometric parameters such as chest circumference,[6] mid-arm measurement,[7] and foot length[8] have been used to identify low birthweight and a newborn at risk. The World Health Organization has studied the chest and arm circumferences in correlation with birthweight, aiming to develop chest or arm bands that would indicate that the birthweights are above or below a specified cutoff point (i.e., 2500 g). However, no effort has been made to correlate anthropometric parameters with actual birthweight. This study uses multiple parameters of chest and arm circumferences and the length of a newborn to estimate birthweight and to validate this new method in various centers throughout Thailand.

Methods

The Training Data Set

The training data set undertaken at the Department of Pediatrics, Lerdsin Hospital, from January to March 1985, involved 402 newborn babies, 197 male and 205 female. The duration of pregnancy at the time of delivery ranged from 36 to 40 weeks according to Nägele's formula. The measurements taken within 24 hours of birth included chest circumference at nipple line in centimeters, arm circumference, midway between the acromion process and the tip of elbow in centimeters, crown-to-heel length in centimeters, and weight in grams.

Measuring Instruments

The measuring instruments consisted of a tailor's metric measuring tape, tested against a standard ruler, and a baby metric beam balance (SECA, made in Germany), tested for accuracy with standard weights. All measurements were performed by the same pediatrician throughout the study.

Sample Size

The sample size was calculated after Lachin[9] to estimate the sample size for the correlation (r) .85, setting $\alpha = .05$ and the power of test at .80 (for a two-tailed test).

Data Analysis

Stepwise multiple regression analysis was employed to formulate the best linear prediction equation.[10] The least squares method was used for fitting the "best" straight line to a given set of data in order to relate two variables.

Testing Data Set

The testing data set of body weight and chest and arm circumferences of 3222 newborn infants from eight hospitals in north, northeast, central, and south Thai-

land was used for analysis. Measurements were taken within 24 hours of birth. The study population was derived from two sets of data. The first set consisted of 1612 newborn babies from the project "Low Birth Weight Newborn Babies of High Risk Mothers" at Chulalongkorn University Hospital, and at regional maternal and child health hospitals in Chiengmai, Nakornsawan, Rajburi, Yala, and Masharaj Hospital at Nakorn-srithamaraj. This was a case-control study, with a 1:2 ratio of low birthweight (LBW) to normal birthweight infants.

The second set of data consisted of 1610 newborn babies from Lerdsin Hospital and the Khon-Kaen University Hospital in Bangkok.

The first set was collected by nurses, using standardized measuring methods, and the second set was obtained by the doctors responsible for the project.

A diagnostic test was employed to reveal sensitivity and specificity of positive predictive values, negative predictive values, and accuracy of the new device in comparison with the gold standard (a baby metric beam balance) in screening for LBW infants.

Results

The data from the study of 402 newborn babies are summarized in Table 1. The correlation coefficients (r) of weight versus chest and arm circumferences and body length were 0.89, 0.82, and 0.78, respectively.

Although the combined chest and arm circumferences and length gave the best correlation with birthweight ($r = .92$), measuring the length of a newborn baby is usually impractical and may be subject to relatively large error. We therefore chose the second best equation (Table 2), using the combined chest and arm circumferences to estimate birthweight ($r = 0.90$, $r^2 = 82.0\%$, and standard error (SE) = ±183.3 g). Based on this equation, a nomogram was constructed (Figure 1) and, subsequently, a circular birthweight estimation device was developed (Figure 2).

The mean and standard deviations (SD) of chest and arm circumferences of 3222 newborn babies in various study centers are shown in Table 3. The mean of chest circumferences was about 31 cm, and arm circumferences was about 10 cm.

The differences of means between the weight obtained by standard scales and the estimated weight obtained by the new device (Figure 2) are also shown. The differences appear to be within ±187 g.

The diagnostic values of the new device, when the arbitrary point for picking LBW infants is set at 2500 g, are shown in Table 4. The sensitivity was lowest (56.9%) at Nakornsawan and highest (94.5%) at Chulalongkorn hospital. The specificity was lowest (86.1%) at Khon-Kaen and highest (98.6%) at Yala. The accuracy varied from 83.2% to 95.7%.

If the arbitrary point for defining LBW neonates is set at 2600 g on the new device, the sensitivity at all centers increased, ranging from 71.3% to 97.3%, the specificity ranged from 78.4% to 97.2%, and the accuracy ranged from 79.8% to 92.3%, as shown in Table 5. If the arbitrary point was set at 2700 g, the sensitivity increased to 100% at Chulalongkorn Hospital but the specificity declined to 58.7% at Khon-Kaen Hospital (Table 6).

These results showed that the optimum arbitrary point of all data combined for defining LBW neonates when using the new device should be 2600 g and can be confirmed by the receiver operating characteristic curve shown in Figure 3. The curve became steeper when the arbitrary point was changed from 2500 g to 2600 g, which means that the sensitivity increased markedly while only a small degree of specificity was lost. However, the curve became linear when the arbitrary point was 2700 g, which indicates a very small increase in sensitivity but marked loss of specificity.

Discussion

Birthweight of infants estimated from the Chulalongkorn birthweight estimation device differed by only ±187.4 g from weight obtained by a standard scale. This difference is not clinically significant unless the birthweights are below 2000 g.

The sensitivity and specificity of the new device varied when arbitrary points of LBW infants were set at 2500, 2600, and 2700 g. There was less variation in accuracy, however. The optimum arbitrary point on the new device, as determined by a receiver operating characteristic curve, was found to be 2600 g. The sensitivity increased to 100% when the arbitrary point was 2700 g, but the specificity was low, indicating that there would be an increased number of falsely identified LBW infants.

The Chulalongkorn birthweight estimation device appears promising as an appropriate substitute for obtaining the birthweight of newborns in places where scales are not readily available. While the theoretical error was ±183.3 g, the prac-

−PV (%)	98.9	—	—	—

Note. +PV, positive predictive value; −PV, negative predictive value; positive and negative predictive values of case-control study cannot be calculated, since estimates of prevalence of low birthweight were not available.

LS = Lerdsin General Hospital; KK = Khon-Kaen University Hospital; CU = Chulalongkorn University Hospital; CM = Chiengmai MCH Hospital.

tical error was ±187.4 g when compared with standard weighing scales.

The diagnostic test revealed the value of the new device. The optimum arbitrary point for screening an LBW infant was 2600 g, at which the sensitivity was 97.3%, the specificity was 97.2%, and the accuracy was 92.3%. This new device is inexpensive and convenient and is a good example of appropriate technology for primary health care. Use of the device should be encouraged throughout developing countries such as Thailand. ☐

Acknowledgments

The authors are grateful to Assistant Professor Supudda Pawanarit of the Department of Mathematics, Faculty of Science, for valuable suggestions concerning the mathematical formulas used in this study. They also wish to thank Dr. Prathan Kanchanalai, Head of the Department of Pediatrics, Lerdsin Hospital, Dr. Dittee Choengcharoen of Siriraj Hospital, and Associate Professor Chitr Sitthi-amorn of Chulalongkorn University for helpful advice. Oral Rehydration Program Evaluation by Quality Assurance Sampling in Rural Haiti

June N. Pierre-Louis, MPH

ABSTRACT

An oral rehydration program in rural Haiti was evaluated by quality assurance sampling. The quality assurance sampling method and its application are described. The indicators measured were knowledge of the oral rehydration salts packet, knowledge of preparation of the solution from the packet, oral rehydration therapy use, and knowledge of preparation of the solution from salt and sugar. Coverages of the first two indicators were adequate, coverages of the latter two were inadequate. The method is a useful low-cost approach to evaluation of program coverage. (*Am J Public Health.* 1991;81:1205–1207)

Introduction

Oral rehydration therapy (ORT) is a cost-effective treatment for diarrheal disease.[1] While the scientific basis for oral rehydration is established, and programs are in place, many programs have not been evaluated at the local level.

In rural Haiti local programs typically target populations of less than 50,000.[2] To meet the need for a low-cost, population-based survey method, quality assurance sampling (QAS), a small sample method,[3] was used to evaluate a local ORT program in Haiti. The QAS method and its application in Haiti are described.

Methods

Study Population

Freres is a rural area located 20 km from Port-au-Prince, the capital of Haiti. The population (13,750 in 1987) lives on dirt roads within one km of a partly paved main road which bisects the area. Freres is targeted by a primary health care program managed by a private hospital in the area. The program maintains a census of the target population.

Promotion of ORT takes place at community meetings and on the radio. Health workers teach mothers to prepare the solution of oral rehydration salts (ORS) from a packet, and from salt and sugar, and to use ORT when their children under three years of age have diarrhea.[2]

Indicators

Widely accepted indicators of program outcome were selected by managers and funders of oral rehydration programs in Haiti and included: ORT use, knowledge of the packet, knowledge of preparation of the solution from the packet, and from salt and sugar.[4,5] The use rate was defined as the proportion of episodes of diarrhea in children under three years of age receiving ORT, whether the solution was prepared from the packet or salt and sugar.[4] The rate of knowledge of preparation of the solution was defined as the proportion of mothers of children under age three knowing the correct quantities of ingredients in a solution prepared from the packet or from salt and sugar.

The survey questionnaire is given in the Appendix.

Quality Assurance Sampling Method

The QAS method was first used for quality control in manufacturing. Product quality was assessed based on the probability of observing a particular proportion of defective items in a sample relative to a null hypothesis stating a proportion of defective products. This probability is determined by the binomial distribution. The goal of the QAS method is hypothesis testing rather than parameter estimation. The major advantage of QAS is the sample size which is small.

TABLE 1—Hypothesized Proportions of Nonrecipients and Recipients, Null Hypotheses and Sample Sizes, Oral Rehydration Program Evaluation, Quality Assurance Sampling, Freres, Haiti, 1987

Indicator	Hypothesized Proportion of Nonrecipients P_0	Hypothesized Proportion of Recipients/ Short-term Program Goal $1-P_0$	Null Hypothesis	Sample Size n	Critical Number Nonrecipients d^*
ORT Use	0.95	0.05	$P_0 \geq 0.95$	20	17
Knowledge of Packet	0.30	0.70	$P_0 \geq 0.30$	45	9
Knowledge of Preparation from Packet	0.70	0.30	$P_0 \geq 0.70$	45	27
Knowledge of Preparation from Salt and Sugar	0.90	0.10	$P_0 \geq 0.90$	45	37

TABLE 2—Coverage and Estimated Proportions of Nonrecipients and Recipients, Oral Rehydration Program Evaluation, Quality Assurance Sampling, Freres, Haiti, 1987

Indicator	Sample Number Nonrecipients d	Critical Number Nonrecipients d^*	Coverage	Estimated Proportion of Nonrecipients	Estimated Proportion of Recipients
ORT Use	19	17	Inadequate	≥0.95	<0.05
Knowledge of Packet	8	9	Adequate	<0.30	≥0.70
Knowledge of Preparation of the Solution from Packet	25	27	Adequate	<0.70	≥0.30
Knowledge of Preparation of the Solution from Salt and Sugar	40	37	Inadequate	≥0.90	<0.10

The rate or coverage of use of ORT in the target population, for instance, is determined to be adequate or inadequate based on finding a certain proportion of children under age three not receiving the benefits of ORT in a sample. The null hypothesis is that ORT coverage is inadequate; that is, the proportion of nonrecipients in the sample is greater than some hypothesized proportion of nonrecipients based on short-term program objectives (see Table 1). The null hypothesis is so stated to control the probability of concluding that a community has adequate health coverage when it is actually inadequate. The probability of such a false negative result was set at 0.10, (α). This error is more serious than a false positive error (β) in which the conclusion is that health coverage is inadequate when it is really adequate.

The following expression holds:[3]

$$\alpha = \Pr\{d \leq d^*\}$$

where d is the observed number of nonrecipients in the sample and d^* is the critical number of nonrecipients in a given sample size. When $d \leq d^*$ the null hypothesis that coverage is inadequate is rejected and it is concluded that coverage is adequate.

The critical number of nonrecipients in the sample was calculated by:[3]

$$d^* = nP_0 - z_\alpha\,[nP_0(1 - P_0)]^{1/2}$$

where n is the sample size; P_0 is the hypothesized proportion of nonrecipients; $1 - P_0$ is the hypothesized proportion of recipients; and z equals 1.28 for α equal to 0.10 using a one-sided test. Fractions were rounded down to the next whole number.

Null hypotheses and values of P_0, $1 - P_0$, n and d^* are given in Table 1 for each indicator.

Sample sizes were obtained from tables developed by Lemeshow, *et al.*,[6] of (n, d^*) pairs for selected values of α, β, and P_0. Values of β are estimates of the difference between true and hypothesized proportions of nonrecipients. A sample size of 45 was chosen for the indicators except ORT use. A mother was asked about ORT use only if she said her child had diarrhea in the past two weeks to minimize recall bias. Sixty-three mothers were interviewed, of which 20 had children under age three who had diarrhea in the past two weeks.

A systematic sample was drawn from the census of the target population maintained by the primary health care program.

The nonresponse rate was 9 percent.

Results

Coverages of ORT use and of knowledge of preparation of the solution from salt and sugar of mothers of children less than three years of age were determined to be inadequate (Table 2). The ORT use rate was estimated to be <0.05. The rate of knowledge of preparation of the solution from salt and sugar was estimated to be <0.10.

Coverages of knowledge of the packet and of preparation of the solution from the packet of mothers of children under age three were determined to be adequate. The rate of knowledge of the packet was estimated to be ≥0.70. The rate of knowledge of preparation of the solution from the packet was estimated to be ≥0.30.

Discussion

The QAS survey in Freres revealed that the primary health program had inadequate coverage of ORT use in the target population despite adequate rates of knowledge of the packet and of preparation of the solution from the packet. The probability that the latter two rates are false negative results is ≤0.10.

The estimated ORT use rate in Freres in 1987 (<0.05) was much lower than the rate for Haiti in 1985 (0.23 of mothers of children less than five).[7] The estimated rate of knowledge of the packet in Freres

(≥0.70) was similar to the national rate in 1985 (0.58).

The QAS evaluation was relatively low-cost because the sample size was small. One interviewer was required for the survey and the evaluation was completed in two days. The QAS method is useful for evaluation of local oral rehydration programs in Haiti. ☐

Acknowledgments

I express my appreciation to Jean-Jacques Lamour for his assistance in the training and supervision of the Freres health workers. This research was supported by a USAID grant to the *Institut Haitien de l'Enfance* and the Haitian Arab Center, Port-au-Prince, Haiti.

Impaired and Disabled Elderly in the Community

Amasa B. Ford, MD, Ann W. Roy, PhD, Marie R. Haug, PhD, Steven J. Folmar, PhD, and Paul K. Jones, PhD

ABSTRACT

A nine-year representative, longitudinal study of 1,598 urban elderly shows that two to eight times as many impaired or disabled are cared for in the community as in institutions. Younger age, male gender, better income, and living with others, especially children, favor continuing care in the home. (*Am J Public Health.* 1991; 81:1207–1209)

Introduction

The purpose of the present study is to report information about the distribution between community and long-term institutional care of a representative sample of urban elderly over a nine-year period. We identify supporting factors that have enabled from two to eight times as many of the most impaired and disabled to remain in the community as were admitted to long-term nursing home care.

Methods

In 1975 a random sample of 1,598 noninstitutionalized persons age 65 years and older, living in the City of Cleveland, Ohio, were interviewed in their homes using the Duke OARS instrument.[1,2]

Nine years later, in 1984, the vital status of all but 13 individuals (0.8 percent) was ascertained. Among the 805 who were known to have survived, 647 (80.4 percent) were reinterviewed, using the same instrument. Information sufficient to determine institutionalization was ob-

Died between 1975 and 1984 (= 1)	.56	.38–.83

[a] 82 cases omitted from analysis because of missing data.

tained for 589 of the living respondents (91 percent). By 1984, 780 individuals were known to have died. Telephone interviews with next of kin or other informants were obtained for 639 deceased, with data about institutionalization secured for 632 (81 percent).

Demographic information was collected according to the OARS instrument. Impaired physical health was indicated by the presence of four or more self-reported chronic conditions from a list of the 12 most prevalent conditions.[3] Impaired cognitive function was measured by a score of four or more errors on a 10-item test of cognitive function.[4] "Psychological distress" was measured as seven or more symptoms of a list of 15 on a Short Psychiatric Evaluation Schedule.[5] Functional disability was measured by need for help with one or more of six activities of daily living: walking, going outside, bathing, dressing, transfer (i.e. getting in or out of bed or chair), or eating.[6]

The definition of long-term institutionalization was one or more institutional admissions totaling 30 days or more during the nine-year observation period, or prior to death. The rest of the subjects were characterized as "remaining in the community," even though they may have experienced short-term admissions. The object was to distinguish those who continued to receive care mainly outside of institutions from those who entered long-term or indefinite institutional care.

Results

Comparison of the 1984 survivors with figures extrapolated from the 1980 census of Cleveland shows that the subjects, now aged 74 years and older, remained representative of the city population aged 75 and over.[7]

By 1984, 76 of the 647 responding survivors (11.8 percent) were living in an institution at the time of the interview, and a total of 63 (10.7 percent) of all respondents, including institutionalized and noninstitutionalized, had been admitted to a long-term care institution for 30 days or more. Of 731 persons who died during the nine-year observation period and for whom death certificates were available, 28.3 percent had a nursing home as their usual place of residence at the time of death.

Considering first the 589 survivors with complete data and their state of health impairment and functional disability at the time of reinterview in 1984, it appears that mental health impairment and functional disability were associated with institutionalization, but that the chances of remaining in the community were not affected by the presence of multiple chronic conditions. Expressed as a ratio of numbers of community residents to numbers of institutional residents, the figures are 7.8 for physical health impairment, 2.4 for cognitive impairment, 2.3 for psychological distress, and 1.8 for functional disability (Table 1).

The next stage of analysis was to ask whether it would have been possible to predict at the beginning of the study who would experience long-term institutionalization and who would remain in the community. A multivariate logistic regression was performed, using remaining in the community as the dependent variable, with independent variables as indicated in Table 2.

Factors significantly favoring continued care in the community include: younger age, male gender, income of greater than $5,000 (1975), and living with child(ren) only. Since previous analyses had pointed to living with others as favoring community care, three separate regressions were carried out, using different definitions of this variable. The odds ratio resulting were: lives with spouse, or children and spouse: 1.76 (95% CL = 1.08, 2.89), lives with others: 2.23 (95% CL = 1.54, 3.22), and lives with child(ren) only: 3.45 (95% CL = 1.85, 6.43).

Somewhat surprisingly, none of the four measures of impairment or disability served to distinguish between those who remained in the community and those who experienced long-term institutionalization. Those who died during the study period were less likely to have avoided long-term institutionalization.

Discussion

These results indicate that socioeconomic factors predominate as predictors of long-term care in the community. The way these factors operate is fairly clear. Relative youth implies better resources and coping skills. Males are more likely to have a surviving spouse. Better income allows for better housing and purchase of services, and children can be both care providers and income producers. In other recent longitudinal studies age, female gender, and living alone or absence of spouse have been shown to predict institutionalization.[8,9] Notably in the present study, when elders live with them, children appear to enhance the possibility of remaining in the community more than do living spouses or nonspecified "others."

Although, in this study, impairment and disability do not appear to predict whether community or institutional care will be used, it must be remembered that some part of nine years intervened between the measurement of dependent and independent variables. Observations closer to the decision-point might have shown that mental health impairment and functional disability were more difficult to care for at home than impairment of physical health alone, as suggested by the data in Table 1. ☐

Recent Trends in the Incidence of Toxic Shock Syndrome in Northern California

ABSTRACT

The incidence of toxic shock syndrome in women members of a large prepaid medical care program in Northern California was 1.5 cases per 100,000 in a period after removal of tampons containing polyacrylate rayon and reductions in tampon absorbency. This rate was lower, but not significantly lower, than the rate of 2.2 per 100,000 in the prior interval. It was higher, but not significantly higher, than the rate of 0.4 per 100,000 in the era before "superabsorbent" materials were introduced into tampons. The incidence in men has been stable at about 0.1 cases per 100,000 for the 15-year period from 1972 though 1987. (*Am J Public Health.* 1991;81:1209–1211)

Diana B. Petitti, MD, MPH, and Arthur L. Reingold, MD

Introduction

We previously reported the incidence of toxic shock syndrome (TSS) through 1985 in members of the Northern California Kaiser Permanente Medical Care Program ages 15–34 years.[1–3] Here, we present a final update on TSS in this population, presenting data for 1986 and 1987. The incidence of TSS in these latter two years is of particular interest, because polyacrylate rayon, a material included in tampons to increase their absorbency, was removed from tampons marketed in the United States in March 1985 and because there were further declines in the absorbency of tampons overall. Since high absorbency has been linked with an increase risk of TSS in tampon users,[4] one would expect the incidence of TSS to decline in women after reductions in the absorbency of tampons brought about, at least in part, by removal of polyacrylate rayon from tampons.

Methods

Our method of case ascertainment, in which medical records were reviewed to identify recognized and unrecognized cases of TSS, was described in detail in a

TABLE 1—Incidence of Definite TSS in Females Ages 15–34 in Relation to Certain Milestones in Tampon Formulation and Marketing

Time Periods	Description	Number of Cases	Incidence* (95% Confidence Interval)
1. 1972–June 1977	Prior to introduction of superabsorbent materials	5	0.4 (0.1,1.0)
2. July 1977–April 1979	After superabsorbents introduced, but before Rely marketing in California	8	1.5 (0.6,2.9)
3. May 1979–September 1980	Rely and other superabsorbents in California	11	2.4 (1.2,4.2)
4. October 1980–March 1985	After Rely removal from the market but before removal of polyacrylate rayon	34	2.2 (1.5,3.0)
5. April 1985–December 1987	After removal of polyacrylate rayon products and reductions in absorbency	14	1.5 (0.8,2.6)

* per 100,000 women-years

prior publication.[1] Briefly, we used computer-stored information from records of discharges from Northern California Kaiser Permanente Medical Care Program facilities for the period 1972 through 1987 to identify men and women ages 15–34 years hospitalized with illnesses that might be confused with TSS, or, for later years, with diagnosed TSS. Records for qualifying hospitalizations were reviewed by a single trained medical record technician, who determined whether or not the illness met the case definition for TSS developed by the Centers for Disease Control (CDC), except that desquamation and orthostatic dizziness were not considered criteria because desquamation was not reliably recorded in the medical records and because orthostatic hypotension was not an official criterion for TSS when the study began. Records for all illnesses that might represent TSS were then reviewed independently by each of the co-authors, who classified them as definite TSS, probable TSS, or not TSS. Definite TSS cases were illnesses that met all the CDC criteria as TSS, except desquamation. Probable cases were illnesses that had rash, fever, and hypotension, but involved only two organ systems.

The denominators for the calculation of the incidence rates were person-years of membership in the Northern California Kaiser-Permanente Medical Care Program. Ninety-five percent confidence intervals were estimated based on the assumption that the incidence of TSS is distributed as a Poisson. Statistical tests of the hypotheses about rates of TSS were carried out based on the comparison of two Poisson variables.

Results

Table 1 shows the incidence of definite TSS in women in relation to certain milestones in tampon formation and marketing. The incidence of TSS was statistically significantly higher (p = 0.0003) after introduction of superabsorbent materials and Rely tampons into the California market (period 3) than in the period prior to these two changes in tampon for-

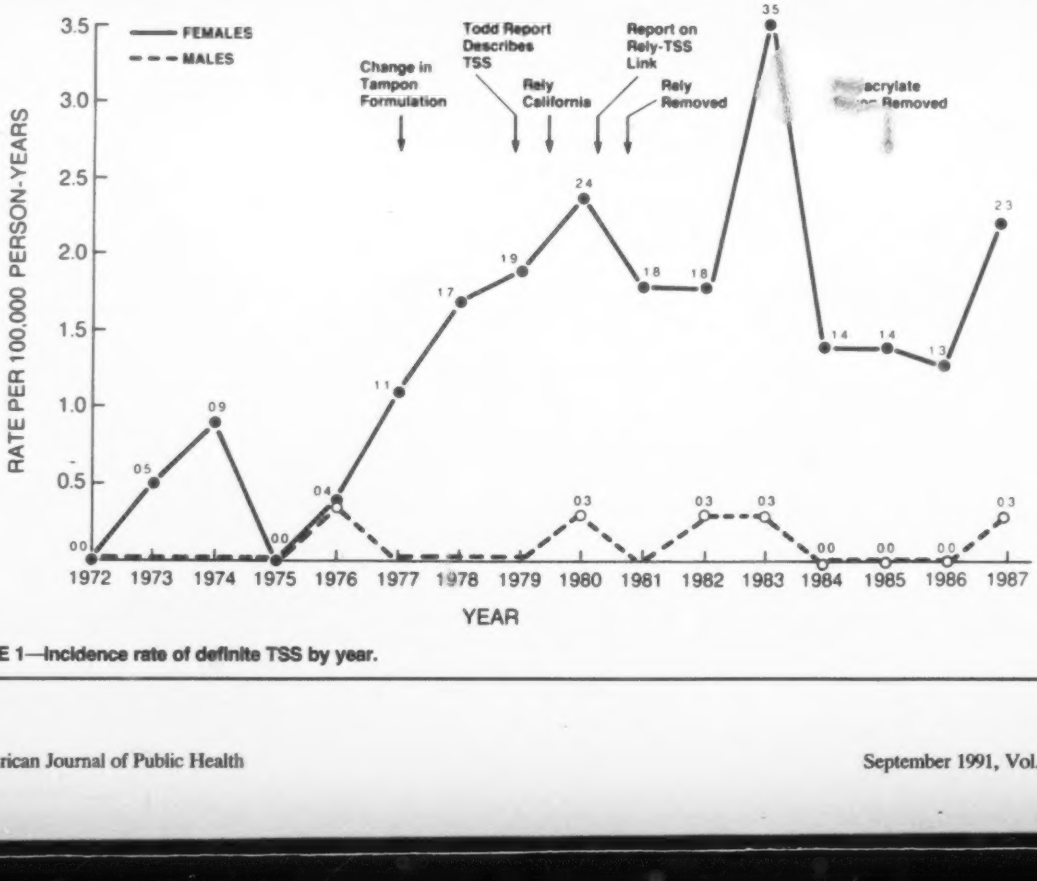

FIGURE 1—Incidence rate of definite TSS by year.

mulation and marketing (period 1). The incidence of definite TSS in women after removal of Rely and polyacrylate rayon from remaining tampons (period 5) was lower, but not significantly lower ($p = 0.13$) than in the prior two intervals (periods 3 and 4). The incidence rate after removal of polyacrylate (period 5) was also not statistically significantly higher ($p = 0.13$) than in the period prior to introduction of superabsorbent materials (period 1).

Information on menstrual status at the onset of symptoms was retrievable from the medical records of all 12 definite TSS cases in women in 1986 and 1987 (Figure 1). Eight of these cases (67 percent) were menstrual (95% CI = 49, 85). This percentage is the same as it was in prior years in this population.[2]

The incidence of TSS in men has been stable at about 0.1 cases per 100,000 throughout the 15-year period covered by this surveillance project.

Discussion

The incidence of TSS began increasing in about 1977 in temporal relation to changes in tampon formulation that made them more absorbent. The rarity of TSS in this population limits the ability to draw firm conclusions about the incidence of TSS in relation to the removal of Rely tampons from the market, the subsequent removal of polyacrylate rayon, and the reductions in the absorbency of tampons that occurred simultaneously. The data are suggestive of a decline in incidence in relation to removal of polyacrylate rayon and accompanying reductions in absorbency. However, these changes in tampon formulation have clearly not eliminated TSS in women.

It is reasonable to conclude TSS is very rare in men. It also appears that in this population the percentage of menstrual cases is stable at about two-thirds of all cases in women. The incidence in both men and women in this population is very low, and TSS is not an important public health problem at this time. ☐

Acknowledgments

This research was supported by a grant from the California Public Health Foundation with funds from the Proctor & Gamble Corporation. We are indebted to Beverly Whitmarch for reviewing the medical records.

Hospital Charges in Five Washington Counties Jump Average of Nearly 37%

Hospital charges in the state of Washington's five largest counties increased by an average of nearly 37% between 1987 and 1989, according to a report by the Washington State Department of Health.

The report, "Inflation Measures in Hospital Charges," covers 15 separate categories, from coronary bypass surgery to Caesarean delivery, at hospitals in King, Pierce, Snohomish, Thurston, and Spokane Counties.

"Hospital charges climbed at a significant rate over that 3-year period," said State Health Secretary Kristine M. Gebbie. "This report confirms that the issues surrounding the inflation of hospital charges are complex and that the upper range of these inflation measures are well above the consumer price index or even average increases in medical charges."

Increases in charges over the 3-year period range from 9.9% for treating alcohol and drug dependency to 67.7% for newborn children with major medical problems. Annual inflation figures for those same categories of treatment were 4.1% and 32.8%, respectively, with a median annual inflation rate of 10.5% covering all 15 categories.

The overall average increase for the 15 categories of services was 36.6% over the 3-year period.

The amount of inflation varied by category of service and the county. For example, average charges for cardiac bypass surgery in King County jumped from about $17,500 in 1987 to just over $22,200 in 1989, whereas in Pierce County the charges for similar procedures increased from just under $23,000 to more than $30,000. In Spokane County, similar bypass surgery jumped from about $18,800 to about $21,500.

For this type of bypass surgery, the overall average charge increased from $19,038 to $23,482, or about 23.3%. Annually, this meant the inflation rate for this procedure was 10.7%. The greatest total increase over the 3-year period was 30.8% in Pierce County, and the smallest gain was in Spokane County with 14.6% over 3 years.

Another category, care for newborn children without significant problems, represents the greatest single area of competition between hospitals, according to the state agency's report.

The average charge for newborn care within the five counties increased from $478 for the first half of 1987 to $555 for the second half of 1989, or about 16%. This level of increase did not occur in all counties. Snohomish and Spokane counties posted 20.8% and 28.5%, respectively.

Two measures of inflation are used extensively throughout the report: total change in the average charge from the first half of 1987 through the last half of 1989; and the average annual rate for 1988 and 1989. The report also measures the average level of inflation in charges covering all patients and all categories.

In addition to bypass surgery and Caesarean section deliveries, the 15 categories of service include chemotherapy, reattaching major joints or limbs, and psychiatric care, including the treatment of schizophrenia and manic depression.

Anyone who wants a copy of the report may contact the State Department of Health, Office of Hospital Data Systems, Mail Stop FJ-21, Olympia, WA, 98504, or phone 206/753-1990 during regular business hours.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Michel A. Ibrahim, MD, PhD, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal of APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Sociodemographic Distribution of Gonorrhea Incidence: Implications for Prevention and Behavioral Research

Roselyn J. Rice, MD, Pacita L. Roberts, MS, H. Hunter Handsfield, MD, and King K. Holmes, MD, PhD

ABSTRACT

Background. Despite a declining incidence during the AIDS era, gonorrhea remains the most frequently reported communicable disease in the United States.

Methods. During 1986 and 1987 we supplemented gonorrhea case reporting with laboratory surveillance in King County, Washington. Incidence rates were correlated with demographic variables.

Results. Overall incidence of gonorrhea was similar for men and women, but highest for 16- to 21-year-old females and urban Seattle residents. Incidence rates by ethnicity were Blacks, 3033; Native Americans, 843; Hispanics, 617; Asians, 190; and Whites, 121. Census tracts representing the lowest socioeconomic status (SES) quartile accounted for 58% of reported gonorrhea. Black female teenagers residing in the lowest SES urban areas had highest incidence rates: aged 14 to 15, 3.4%; 16 to 17, 10.4%; 18, 17.0%; and 19, 15.4%. Rates in female teenagers were even higher after adjustment for estimated proportion of those who were sexually experienced.

Conclusions. Gonorrhea incidence is associated with age, gender, ethnicity, SES, and residence. Identification of populations at highest risk for gonorrhea can direct interventions against all sexually transmitted diseases. Clearly, interventions to alter high-risk behaviors must be initiated in early adolescence. (*Am J Public Health*. 1991;81:1252–1258)

Introduction

With the advent of effective contraception, the onset of sexual maturity in the baby boom generation, and changes in sexual behavior, reported cases of gonorrhea increased at about 15% per year from the 1960s through the mid-1970s in the United States.[1,2] Reported cases have gradually fallen since 1975.[3] After 1982 a steady decline in rectal gonorrhea in men was observed in King County, Washington, and in other areas of the United States,[4,5] implying a decline in gonorrhea among homosexually active men. Further analysis of trends in occurrence of gonorrhea by age, gender, and race for the period 1980 through 1988 in King County has shown more than a threefold decline in cases occurring in White men, little change in White women, but a steady increase in Black men and women from 1982 through 1988 (authors' unpublished data). Among Blacks, the greatest increase in annual cases has occurred among teenagers. This unexpected increase in gonorrhea in Blacks and the concurrent leveling off of reported cases in White women after nearly a decade of decline led us to undertake a 2-year intensive surveillance of gonorrhea in Seattle-King County to define incidence rates in population subgroups according to age, gender, race or ethnicity, residence (urban, suburban, or rural), and socioeconomic status (SES). The results are useful not only for defining more precisely a current profile of individuals at highest risk for gonorrhea, but also as a proxy measure of the distribution of sexual behaviors that place individuals at risk for all sexually transmitted diseases, including the acquired immunodeficiency syndrome (AIDS).

Methods

Surveillance and Case Reporting

King County, Washington (population 1.4 million, 2130 square miles), encompasses the city of Seattle (population 496 000). Health care providers in King County are required to report all gonorrhea cases; compliance is 100% by Seattle-King County Department of Public Health (DPH) clinics, but variable by other clinics and the private health care sector.

Surveillance

Beginning in 1985, presentations to microbiology laboratory directors, monthly bulletins of the DPH, newsletters and bulletins of the King County Medical Society, and hospital staff meetings were used to publicize the enhanced gonorrhea surveillance project and encourage compliance with effective culture diagnosis and case reporting. Routine case reporting was supplemented by active laboratory surveillance for *Neisseria gonorrhoeae* in

laboratories in King County through a system established with the DPH central laboratory. Hospital, private physician, and commercial laboratories were asked to submit all positive and confirmatory culture isolates for *N. gonorrhoeae* to the DPH laboratory for confirmation and antimicrobial susceptibility screening tests.

The DPH processed 56 353 cultures for *N. gonorrhoeae* in 1986 and 52 844 in 1987. During 1986 and 1987, gonococcal isolates were received from 14 hospitals, 4 private microbiology laboratories, 2 student health clinics, 2 military health clinics, all 12 DPH clinics, 22 community clinics (partially supported by DPH), the Seattle-King County Jail and Juvenile Detention Center, 6 private family planning clinics, and numerous physicians' offices. Of the cultures confirmed as positive for *N. gonorrhoeae*, 47.0% were submitted from DPH clinics, 22.2% from private physicians, 20.4% from hospitals, 6.0% from community clinics, 3.6% from private family planning clinics, 0.6% from student health clinics, and 0.1% from military clinics. Matching of positive cultures confirmed by the DPH laboratory with submitted case reports from all public and private providers indicated that cultures were submitted to the DPH laboratory for confirmation from 78% of the reported gonorrhea cases in the study population.

Case Reporting

Gonorrhea case reports were submitted to the DPH using Centers for Disease Control (CDC) form 73.688 (revised 1/86). Following notification of a case of gonorrhea by case report form or as a result of laboratory surveillance, when necessary, DPH staff contacted health care providers for additional demographic information on age, gender, race or ethnicity, address, anatomic site of infection, date of infection, date of treatment, and clinical diagnosis (asymptomatic gonorrhea, symptomatic gonorrhea, pelvic inflammatory disease [PID], disseminated gonococcal infection [DGI], adult conjunctivitis).

Demographic Classification

Data from case reports were abstracted and analyzed for all individuals with gonorrhea who resided in King County at the time of diagnosis. Residence was classified as urban for persons residing within the geographic boundaries of Seattle and as suburban for persons living in incorporated areas of King County or in census tracts with population densities of more than 2000 persons per square mile (based on 1980 US Census statistics). The remainder were classified as rural King County residents. Race and ethnicity were classified according to the CDC case report form 73.688 as White, Black, Hispanic, Asian/Pacific Islander, Native American/Eskimo, or other. Hispanics were classified separately, regardless of race designation.

Socioeconomic Categorization of Census Tract of Residence

Census tracts in Seattle were divided into four socioeconomic categories on the basis of the following population characteristics summarized from the 1980 US Census on Population and Housing[6]: (1) median family income; (2) percent that completed high school; (3) percent employed in professional, managerial, or technical occupations; (4) housing cost index; and (5) percent in owner-occupied housing. A score was computed for each tract from the sum of the tract rankings according to the stated characteristics, and these scores were used to categorize tracts into low, lower-middle, upper-middle, and high SES groupings. These four groupings comprised 25.5%, 28.2%, 18.7%, and 27.6% of the city population, respectively.

Calculation of Gonorrhea Incidence

Incidence rates for gonorrhea were calculated using the total number of cases reported to the Seattle-King County DPH in the 2-year period 1986 to 1987, divided by the total county population count from the 1980 US Census of King County population. This was halved to arrive at an annual rate. Incidence rates by gender, age, race or ethnicity, and census tract of residence were calculated in the same way, using 1980 US Census Bureau data for King County.[6]

Calculation of Estimated Incidence Rates by Marital Status

Marital status was not known for 50% of cases reported from sources other than DPH clinics. In order to estimate incidence rates for marital status, the distribution of marital status for cases where this was known was applied to the unknowns.

Calculation of Adjusted Incidence Rates for Sexually Experienced Women

Gonorrhea rates were calculated for women of White and other races using as denominators national estimates of the number of women who were sexually experienced, as reported in the 1982 National Survey of Family Growth Report;[7] these estimates were adjusted for the number of women in King County in 1980 by age and race.

Statistical Analysis

Correlation between incidence rates and population density in census tracts was examined statistically by computing the correlation coefficient (r).

Results

Incidence of Gonorrhea by Age, Gender, Race, Residence, and Marital Status

Gender and Age Group. The overall annualized incidence rates of gonorrhea by gender were 293 per 100 000 for men and 286 per 100 000 for women. As summarized in Figure 1, the incidence of gonorrhea was highest in females aged 16 to 19 years. For ages 16 to 17 years, incidence rates of gonorrhea were four times higher for females than for males. In contrast, gonorrhea incidence among men was more broadly distributed across age groups, but was higher for men than for women above age 24. Men and women in the 22- to 24-year-old age group had similar rates of gonorrhea.

Race and Ethnicity. Of the 7342 reported gonorrhea cases, 39.6% involved Whites, 48.8% Blacks, 3.3% Native Americans, 3.5% Asians and Pacific Islanders, and 4.9% Hispanics. The annual incidence of gonorrhea per 100 000 by race or ethnicity is shown in Table 1.

There were remarkable differences among racial and ethnic groups in the age and gender distribution of gonorrhea incidence. Among men, the peak incidence of gonorrhea per 100 000 was observed at age 19 for Blacks (11 266) and Native Americans (2299), age 20 for Asians and Pacific Islanders (807), age 21 for Whites (283), and ages 22 to 24 for Hispanics (2597). Among women, the peak incidence per 100 000 was observed at age 18 for Blacks (12 848), Whites (729), and Hispanics (906), and age 19 for Native Americans and Eskimos (6250) and Asians and Pacific Islanders (1068). The overall male:female ratio for gonorrhea incidence was 1.18 for Blacks, 0.73 for Whites, 0.48 for Native Americans, 1.50 for Asians and Pacific Islanders, and 3.51 for Hispanics. As shown in Figure 2, the gender ratio for gonorrhea incidence followed a similar pattern for Whites and Blacks, with females predominating at younger ages and males predominating at ages 25 to 29 years

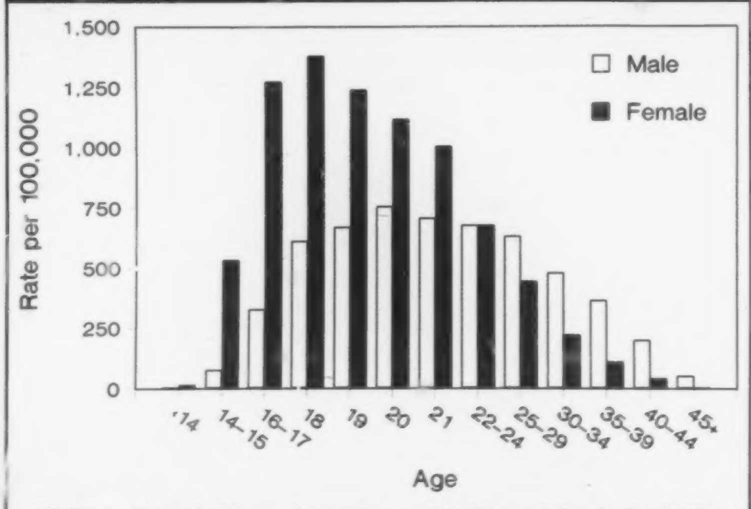

FIGURE 1—Annual incidence of gonorrhea per 100 000 population for Seattle-King County residents by gender and age group, 1986–1987.

TABLE 1—Annual Incidence of Gonorrhea per 100 000 Urban Residents of Seattle According to Race or Ethnicity and Socioeconomic Status (SES), 1986 and 1987

Race or Ethnic Group	SES of Residence Census Tract				All SES Groups
	Low	Lower-Middle	Upper-Middle	Upper	
White	386	153	104	78	121
Asian	310	214	181	125	190
Hispanic	1796	527	427	302	617
NA[a]	1961	1003	640	519	843
Black	3394	3018	2305	1990	3033
All race or ethnic groups	1147	421	224	183	289

[a] NA=Native American.

and above for both groups. However, for Hispanics, rates for females exceeded rates for males only for ages 17 years and under and were about threefold to sixfold lower after age 21. Similarly, for Asians and Pacific Islanders, the incidence in males exceeded that for females for all ages after age 19 and remained low thereafter. In contrast, for Native Americans the incidence rates for females were higher than incidence rates for males for all ages up to 35 years. These differences are large, but are based on relatively small numbers of cases involving Hispanics, Asians and Pacific Islanders, and Native Americans and Eskimos. The differences could also be influenced by underreporting of male cases, as discussed below.

Marital Status. The annual adjusted incidence of gonorrhea per 100 000 was 42 for married men; 67 for divorced, separated, or widowed men; and 1018 for never-married men. The incidence per 100 000 was 33 for married women, 21 for divorced, separated, or widowed women; and 1275 for never-married women. We did not adjust further for marital status in subsequent analyses because data on marital status were not available for all cases.

Urban, Suburban, and Rural Residents. Of the 7342 gonorrhea cases included in this analysis, 74% occurred in urban (i.e., Seattle) residents, 19% in residents of suburban census tracts with ≥2000 residents per square mile, and 7% in residents of rural census tracts (<2,000 residents per square mile). The annualized incidence rates per 100 000 were 555 for urban residents, 143 for suburban residents, and 86 for rural residents.

Socioeconomic Status. In Seattle, which we defined as urban, the population living in low SES census tracts represented only 25.5% of the population but accounted for 58% of the reported gonorrhea. There were 2870 cases in 125 143 residents of low SES census tracts, 1164 cases among 138 294 residents of lower-middle SES census tracts, 409 cases among 91 407 residents of upper-middle SES census tracts, and 494 cases among 135 262 residents of high SES census tracts.

Annual incidence rates according to race or ethnicity and SES are shown in Table 1. Within each racial or ethnic group, there was an inverse and statistically significant relationship between gonorrhea incidence and the SES of the census tract of residents ($P<.01$ for each group). Within each SES grouping, the relative incidence rates by race and ethnicity generally corresponded to the unadjusted relative rates, but the magnitude of the differences by race and ethnicity was reduced. For example, the overall incidence rate was 25 times greater for Blacks than for Whites, but among those of lowest SES the rate was 8.8 times greater for Blacks than for Whites.

Incidence in Female Residents of Low SES Urban Census Tracts. Because the highest incidence of reported gonorrhea occurred in urban census tracts of low SES, and because the completeness of surveillance for laboratory-confirmed gonorrhea may have been highest for females (see Discussion), we further analyzed the incidence rates among women within these census tracts according to age and race or ethnicity. As shown in Figure 3, the highest incidence rates were observed in Black female teenagers, among whom the highest annual incidence reached 17 040 per 100 000 at age 18 and declined thereafter.

Correlation of Gonorrhea Distribution and Incidence with Population Density and Residence. The incidence of gonorrhea by census tract was directly but weakly correlated with population density ($r=.55$, $P=.02$). Mapping of gonorrhea incidence indicated two clusters of high-incidence census tracts, each with ≥1000 cases of gonorrhea per 100 000 population per year, in central and south Seattle (Figure 4). These clusters corresponded to those tracts with the lowest SES rankings and with the highest proportions of non-White residents.

Estimated Incidence Rates in Sexually Experienced Women. By adjusting the denominators to represent only the estimated number of women who were sexually experienced,[7] as advocated by others,[8] the greatest effect on estimated incidence rates was observed, as expected, among teenagers. Regardless of race, adjusted incidence rates increased by about four- to sixfold in 15-year-old adolescent women and by 1.2 to 2.9 in groups of 16- to 17-, 18-, and 19-year-old women (Table 2).

Distribution of Cases by Provider Source. The distribution of gonorrhea by gender, age, and race or ethnicity was compared for cases reported from (1) DPH clinics; (2) hospitals, community clinics, and private physicians; and (3) private family planning clinics. Public clinics reported 56% of cases in males and 38% of cases in females. DPH clinics reported 991 (68%) of 1457 cases in Black men aged over 20 years, vs 545 (58%) of 942 cases in White men of the same age. Otherwise, the distribution of cases by age, sex, and race was not substantially different between DPH clinics and the other groups of providers.

Complications of Gonococcal Infection. Of all women with gonorrhea, 18% received a clinical diagnosis of PID, including 20% of Native Americans, 19% of Whites, 18% of Blacks, and 8% of Hispanics. Fifteen cases of DGI were reported, representing 0.2% of all gonorrhea cases; women accounted for 12 (80%) of these 15 cases. Six cases of adult gonococcal conjunctivitis were diagnosed during the 2-year period. Data were inadequate for estimating the incidence of epididymitis.

Discussion

The distribution of gonorrhea incidence in King County varies markedly according to age, gender, race or ethnicity, and residence. Among individuals classified by age and gender, by far the highest incidence was observed for 18-year-old women, and among adolescents, the ratio of female to male cases was highest for those 14 to 17 years of age. This fact would be obscured by aggregating data into 5-year age groups as in national data sets for sexually transmitted diseases. In explaining these differences in gonorrhea incidence in adolescent males and females, the relative contribution of differences in exposures and differences in host susceptibility remains to be determined. For men and women, the incidence of gonorrhea is highest among certain ethnic minorities living in urban, lower SES census tracts.

A critical feature of this analysis is the adequacy of surveillance. Was case detection representative and complete, or was it incomplete and biased? Evidence for completeness in surveillance includes

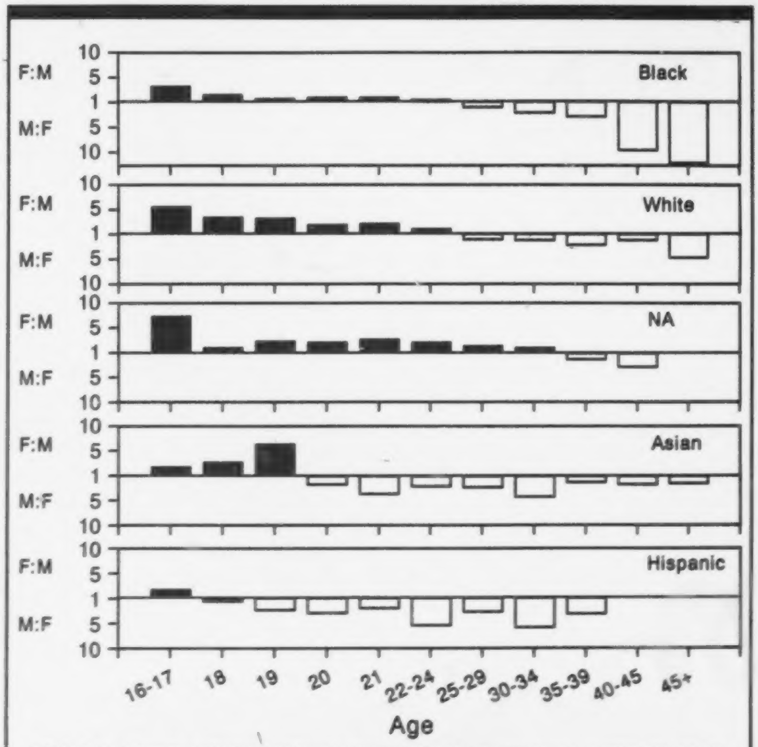

FIGURE 2—Gender ratio for incidence of gonorrhea by age and race or ethnicity. Solid bars above the line indicate a higher incidence in females than in males for that age and race or ethnic group; open bars below the line indicate a higher incidence in males than in females. NA = Native American Indian.

[a]Crude and adjusted gonorrhea incidence rates did not change substantially among women aged ≥ 25 years.[9]

the one-to-one male to female ratio of reported cases; the similar distribution by age, gender, and race or ethnicity of cases from various reporting sources, with the exception noted; and the fact that 53% of cases (44% of males and 62% of females) were reported from non-DPH sources. Nationally, for 1987, only 32% of cases of gonorrhea were reported by private providers.[3] Further, virtually all community clinics, which are partially supported by DPH, use the DPH laboratory for gonorrhea culture diagnosis. Almost all major hospitals and their associated clinics in King County reported cases of gonorrhea through their laboratories during the study period, and these laboratories as well as most commercial laboratories submitted gonococci to the health department laboratory for confirmation and determination of antimicrobial susceptibility.

Regarding reporting of gonorrhea in males, in a unique study of gonococcal urethritis in King County that involved active surveillance of male patients of a sample of private physicians during 1974 and 1975, it was estimated that 38% of cases of gonococcal urethritis were seen in DPH clinics and 62% by all other reporting sources.[9] Some cases in men seen by non-DPH providers were identified by Gram-stained smear of urethral exudate. The proportion of cases of gonorrhea in men that was seen by non-DPH providers in the present study (44%) was lower than the 1974–1975 estimate, and we assume that some cases of gonorrhea in men are still diagnosed by Gram stain, so that no gonococcal isolate would have been sent to the DPH laboratory. It is thus probable that the proportion of cases of unreported gonorrhea seen in the private sector is somewhat higher for men than for women. Thus, we are most confident of the surveillance data for women. It is likely that some of the differences between racial and ethnic groups in the female-to-male ratio for gonorrhea incidence rates could be influenced by underreporting of gonorrhea in men seen in the private sector. However, we think it is unlikely that this could account for the major differences between racial minority groups in the female-to-male ratio and should not account for the steady decline in the female-to-male ratio with increasing age that was observed for most groups.

Even with enhanced surveillance of gonorrhea, cases in males most likely represent incident cases (new infections), while cases in females represent a mixture of incident cases and prevalent cases of uncertain duration: the shorter the duration, the closer the approximation to incident cases. Thus the comparison of male rates to female rates is not straightforward. It is uncertain how age and race or ethnicity influence the duration of infection at the time of diagnosis among women, but again, it seems unlikely that such influences would account for the differences shown in Figure 2.

The 1980 census data for King County were used to estimate the size of the population subgroups at risk during 1986 and 1987. From 1980 to 1986, it is estimated that the total population of King County increased by 7.2%, but that of Seattle increased by only 0.4%. It is possible that unequal trends in the size of the King County population belonging to individual racial and racial or ethnic groups between 1980 and the 1986-1987 period of study could lead to overestimates or underestimates of the calculated incidence of gonorrhea. The Office of Financial Management Forecasting Division, State of Washington,[10] in fact, provides estimates on changes in the size of the population of King County by race and Hispanic origin. These estimates are based on the "component method," which adds births, subtracts deaths, and adds the estimated net migration as estimated from school enrollments.

Because information on Hispanic origin, which is not a category of race, was not collected on vital records or school records, estimates of Hispanic population were derived by taking the 1980 census proportions of persons of Spanish origin in individual racial groups and applying them to the 1986 population estimates for racial groups. Washington State estimates that in King County from 1980 to 1986 the number of Blacks increased by 12%; Whites increased by 5%; Hispanics by 36%; Asians and Pacific Islanders by 26%; and Native Americans by 11%. Thus, the calculated incidence figures by race and Hispanic origin as presented in Table 2 probably represent substantial overestimates for Hispanics and Asians/Pacific Islanders, less substantial overestimates for Blacks, and small overestimates for Native Americans and Whites. Nonetheless, the relative incidence of gonorrhea in these racial and ethnic groups remains essentially as indicated in Table 1.

National data on gonorrhea incidence have not been published by race and ethnicity in recent years. Some states do not report data on race and ethnicity to the CDC for data aggregation and analysis. Nonetheless, in an analysis of gonorrhea incidence in New York State, Rothenberg[11] observed that "core" census tracts accounted for a disproportionately high percentage of gonorrhea cases. These were predominantly inner-city, low-SES census tracts with high density populations of ethnic minorities. It has been theorized that such core group populations are important in maintaining a high endemic level of gonorrhea, and that gonorrhea transmission is strongly affected by behavioral interactions within these population subgroups.[12,13] We observed a very strong inverse correlation of gonorrhea incidence with the SES rank of census tract of residence, despite nonhomogeneity with respect to various measures of SES of individuals within census tracts; this was independent of race and ethnicity. Although large differences in incidence rates between racial or ethnic groups persisted after adjustment for SES, the nonhomogeneity of SES for individuals within census tracts represents a limitation of these analyses.[14] Such nonhomogeneity could help account for the increasing relative difference in the ratio of incidence rates in Whites vs other groups as SES of census tract increased (Table 1).

It is important to attempt to define reasons why the incidence of gonorrhea is so unequally distributed and concentrated within certain core populations. Many factors clearly interact to increase the incidence of sexually transmitted diseases within such core groups.[11-13] Race and ethnicity, in particular, are best viewed not as risk factors or determinants of gonorrhea incidence, but as "risk markers" for behaviors of subgroups within racial or ethnic categories that lead to exposure to or persistence of gonorrhea. Sexual behaviors leading to exposure to gonorrhea include early onset of sexual intercourse,[8] large numbers of casual sex partners, and particularly selection of partners who are themselves members of high-risk core groups.[13] Health behaviors leading to persistence or increased transmission of gonorrhea include failure to recognize symptoms of gonorrhea, delay in seeking treatment after onset of symptoms, continued sexual activity after onset of symptoms, delay in notifying sexual partner(s) of exposure to infection, nonuse of barrier prophylaxis, and noncompliance with therapy. These behaviors in turn may be heavily influenced by high prevalence of or exposure to prostitution, illicit drug use, low economic and academic achievement (including unemployment and school dropout), nuclear family disintegration, limited access to health and behavioral intervention resources, delayed or low utilization of available health care resources, and related socioeconomic and environmental factors. Cultural perceptions of health and disease may also play a role in the uninterrupted cycle of gonorrhea transmission in such settings. Cultural factors have been poorly studied and urgently require more careful behavioral research involving population-based samples.

Overall, these data are consistent with theories that subgroups within the general population have extraordinarily high rates of gonorrhea. Individuals within these groups undoubtedly serve as a pool of high frequency transmitters of infection and play an important role in maintaining the incidence of infection in the general population. The implications of these data are that improved efforts to prevent the transmission of gonorrhea should be directed to high-risk and high-prevalence populations. These efforts may require refocusing and careful evaluation of traditional disease control measures, including culture diagnosis, effective treatment, routine screening of gonococcal isolates for antimicrobial resistance, and partner notification. Appropriate reallocation of resources for personnel and clinics in geographic areas more accessible to high-risk communities may be needed. In addition, behavioral interventions must be developed for high-incidence groups. Primary interventions clearly should be initiated no later than age 13 in order to reach teenagers who may be exposed at a very early age not only to gonorrhea, but also to other sexually transmitted diseases. Secondary behavioral interventions for high-risk individuals who present with such diseases are also needed. Development and careful evaluation of behavioral interventions based on current theoretical models of human behavior deserve the highest priority for research.

In summary, data on gonorrhea transmission and incidence within population subgroups can serve as a useful proxy for high-risk sexual behaviors that have implications for the transmission of other sexually transmitted diseases, including human immunodeficiency virus (HIV) infection. The patterns of incidence of gonorrhea observed in this study are similar to patterns of heterosexual transmission of syphilis, chancroid, and HIV, which, like gonorrhea, appear to be concentrated in urban low-SES population subgroups in the United States.[1,15] These data reinforce the need for a reassessment and refocusing of traditional disease control strategies and for development of age-specific and culturally sensitive behavioral and social intervention strategies. ☐

Acknowledgments

We thank John Milberg for mapping the incidence of reported gonorrhea by census tract; Barbara Krekeler and Roger Tulloch for assisting in collection of gonorrhea morbidity reports; laboratory personnel and disease intervention staff of the Seattle-King County

Department of Public Health; and Andrew Blair and Laurie Johnson for preparation of figures and manuscript, respectively.

Most Physicians Receive Income Guarantees, Survey Confirms

The majority of physicians who accept new positions through hospital recruitment programs receive income guarantees, new survey data show. Among the 151 hospitals surveyed by Atlanta-based Jackson and Coker, 91% offer such guarantees, which include practice start-up or development costs and a minimum income level for the physician in the first year of practice.

"Income guarantees are nothing less than security blankets," said Randy Gott, Jackson and Coker's director of research. In most cases, the physician exceeds the guarantee in the first year of practice." In fact, over half of the respondents reported subsidy payments to recruited physicians of less than 25% of the guaranteed amounts.

So intense is competition for physicians among hospitals that 73% of hospitals surveyed reported that they sponsor or subsidize physician searches for existing members of their medical staff. Among the most popular forms of shared participation are reimbursement of candidates' interview expenses, fees paid to physician recruitment firms, reimbursement of candidates' relocation costs, and income guarantees.

But how hospitals choose to use these incentives depends on several factors, including the hospital's location and the physician's specialty, according to Gott. "While a hospital in a major city might entice a physician with free office rent, reimbursement of relocation expenses, and a small financial guarantee, a rural hospital might need to offer that physician a larger and more extended financial guarantee," he said. In addition, income guarantees offered will vary by specialty and will depend upon the physician's earning potential in a specific region.

Income guarantees vary in duration. Sixty-nine percent of hospitals reported that their guarantees last 1 year; and another 21% said that their guarantees last 2 years. Only 6% of hospitals surveyed offered guarantees of 6 months. Gott is convinced that hospitals will increasingly offer 2-year guarantees to physicians in highly competitive specialties where practices tend to develop more slowly.

While 74% of hospitals reported a payback provision as a part of their income guarantees, 30% of those surveyed said they would waive a portion of the amount to be paid back if the physician stayed in the practice for a designated period of time. For example, if a physician remained in the practice for 1 year beyond the guarantee period, the hospital would forgive 33% of the guarantee. But if the physician stayed for 3 years, the hospital would forgive the entire amount to be paid back.

In 33% of hospitals surveyed, physicians can pay back income guarantees by performing a variety of services, including administrative duties (67%), consulting services (30%), emergency department coverage (27%), teaching continuing medical education classes (27%), and caring for indigent patients (27%). Added Gott: "Nearly all hospitals that require a payback allow a minimum of 1 year. They want to make a payback as easy as possible."

Public Health Intervention in a Cocaine-Related Syphilis Outbreak

ABSTRACT

Background. Cocaine users and prostitutes are at high risk for syphilis, but disease control is difficult among these populations. During a cocaine-related syphilis outbreak in Chester, Pennsylvania, in 1989, we conducted a control program at sites where sex and drugs were sold.

Methods. During a 2-week period, investigators recruited persons from these sites for interview, serologic testing, and empiric treatment.

Results. Among 136 persons screened, 25 (18%) had early syphilis and 26 others (19%) had recent sexual contact with early syphilis patients. All were treated at initial screening at a cost of $402 and 12 investigator hours per case, compared to $470 and 20 hours per case when treated during routine investigator activities. This program may have contributed to a short-term decline in syphilis incidence in Chester by reducing the period of infectivity of these patients.

Conclusions. Screening and empiric treatment of persons at sites where sex and drugs are sold can be useful in short-term control of cocaine-related syphilis outbreaks. (*Am J Public Health*. 1991;81:1259–1262)

Jonathan R. Hibbs, MD, and Robert A. Gunn, MD, MPH

Introduction

Syphilis case-finding increased in the United States during the 1980s.[1] Transmission among cocaine users and prostitutes contributes to this problem,[2–4] and the disease is difficult to control in these populations. Syphilis control depends on treatment of patients in the early stages.[5–7] The usual approach is to treat all persons with clinical or serologic evidence of infection and their sexual partners.[8]

The Pennsylvania Health Department noted increased early syphilis case-finding in southeastern Pennsylvania during 1988; one town, Chester, had a fivefold increase during 1988 compared with 1987 (Pennsylvania Department of Health, unpublished data). Because epidemiologic information identified cocaine use and prostitution as risk factors, the Health Department targeted control efforts toward locations thought to be used for the sale of sex and drugs. In contrast to the usual approach, empiric treatment was given to all persons at the time of screening.

Methods

Chester is located 20 miles south of Philadelphia. In 1980, 24% of Chester residents lived at or below the poverty level, and 46% of residents had not graduated from high school.[9] Chester's population was 53% African-American in 1980. Public facilities for sexually transmitted disease (STD) treatment in Chester included a hospital emergency room and two publicly supported STD clinics. In 1988, 9% of syphilis cases in Chester were reported from public clinics.

Primary, secondary, and early latent syphilis (referred to collectively as early syphilis) were defined using generally accepted criteria.[10] Involvement with prostitution was defined as giving or receiving money or drugs for sex within the year prior to interview. Drug use was defined as use of any illicit drug within the year prior to interview. A syphilis contact was defined as any person named as the sexual partner of an untreated early syphilis case-patient within 6 weeks before the case-patient interview.

Health providers and laboratories are required to report to the Health Department all cases of syphilis and all laboratory test results indicative of syphilis. A Health Department investigator interviews the patient. If early syphilis is confirmed, the investigator attempts to interview the patient's recent sexual partners and facilitates medical examination and treatment for them and the case-patient. Investigators are responsible for follow-up of all reportable STDs; however, during the time of the screening program, investigator activities in Chester were devoted exclusively to syphilis.

The syphilis screening and treatment program took place between 4 and 11 PM on 6 days between April 17 and 28, 1989. Persons were recruited for screening at community sites in Chester, then taken to a treatment center. Recruiting sites were

TABLE 2—Cost of Syphilis Control Activities in Chester, Pa, April 15–28, 1989, Syphilis Intervention Program

	Syphilis Control Activities	
Factors	Screening and Treatment Program	Routine Investigator Activities
Investigator hours	300	415
Investigator cost	$ 6,914	$9,564
Other costs	$ 3,143	$ 300
Total costs	$10,057	$9,864
Cases treated	25	21
Hours per case treated	12	20
Cost per case treated	$ 402	$ 469

chosen based on information provided by syphilis patients that drugs or sex were sold nearby. Police agreed that they would be absent from these sites during screening. Disease investigators alerted persons frequenting these sites about the screening program several days before it took place. On 3 days, the treatment facility was the Chester State Health Center, and on 3 days it was a mobile van equipped for patient examination and moved within a block of recruiting sites.

Investigators introduced themselves to all persons found at recruiting sites and invited them to be tested and treated for syphilis. If the person agreed, the investigator transported him or her to and from the treatment site. At the treatment site, clients were interviewed, informed of potential side effects, and asked to sign a consent form allowing syphilis testing and treatment. Consenting clients had blood drawn by a nurse, were examined by a physician, and unless they denied any sexual contacts within the past year were treated for early syphilis.[11] Clients receiving penicillin were asked to remain at the treatment site 10 minutes for observation. Rapid plasma reagin (RPR) tests were performed on all blood samples. Reactive samples were analyzed with the fluorescent treponemal antibody test.

Investigator costs were calculated by adding wages, expenses, and benefits of all investigators in Chester during the screening program. In order to identify the fraction of investigator costs due to the screening program itself, the 300 investigator hours spent on the screening program were divided by the 715 investigator hours spent doing syphilis control in Chester during the weeks the screening program took place. Other screening costs included physicians' and nurses' wages, medications, phlebotomy and injection equipment, and van rental.

Routinely identified case-patients treated at public STD clinics cost the Health Department $20 each for medications and clinical fees. Routinely identified case-patients treated by private physicians cost the Health Department only investigator time; the cost of their treatment is unknown. We calculated exact 95% confidence intervals (CI) for rate ratios (RR)[12] and odds ratios (OR).[13]

Results

During the program, 136 clients were screened, of whom 80 (59%) were male and 127 (93%) were African-American. The median age of screening program clients was 20 years (range=11–52 years). The risk of syphilis was greater among female clients (15/56 [27%] vs 10/80 [13%] among male clients; rate ratio [RR]=2.3; CI=1.1–4.7) and among clients 20 years of age or older (21/71 [30%] vs 4/65 [6%] among younger clients; CI=1.7–13.3).

Among 136 persons screened, 38 (28%) reported cocaine use, and 21 (15%) reported involvement with prostitution. Clients reporting these risk factors had increased risk of syphilis (Table 1). Among 34 clients known to be case contacts, 8 (24%) had early syphilis, compared with 17 (17%) of the 102 clients not identified as case contacts (RR=1.4; CI=0.6–3.1). We treated 114 (84%) of the 136 screening program clients, including all case-patients and case contacts. No adverse drug reactions were noted.

The screening program cost the Pennsylvania Health Department $10 057, of which $6914 (69%) was investigator related (Table 2). Compared with routine investigator activities in Chester during the same period, the screening program cost fewer dollars and fewer investigator hours per case treated.

In the first 32 weeks of 1989 (January 1 through August 12), 302 early syphilis cases were diagnosed among Chester residents—1130 cases per 100 000 persons annually. Case-finding peaked in Chester during the weeks of the screening program (Figure).

Personal characteristics of case-patients diagnosed during the screening program were generally similar to those of routinely reported cases, although the screening program case-patients were slightly more likely to report cocaine use (Table 3). Early latent syphilis was more common among screening program case-patients than among routinely reported case-patients (64% vs 44%; OR=2.2, 95% CI=0.9–5.7), particularly among men (90% vs 50%; OR=9.0, 95% CI=1.2–401).

Discussion

We intervened during the peak of an urban syphilis outbreak. Routine partner notification had limited efficacy in controlling this outbreak in its early stages. Disease control was complicated by the involvement of cocaine users and prostitutes in an economically depressed area typical of urban STD transmission.[14] Multiple anonymous sexual contacts and the illicit nature of prostitution and drug use may limit the effectiveness of partner notification among such populations.[15,16] Increasing the number of investigators,[17] broadening criteria for screening,[18] and

targeting areas where high-risk persons congregate[19,20] may be indicated in STD outbreaks that routine partner notification fails to control. Our intervention combined these elements and added on-site empiric treatment.

We showed that such a program can treat infected persons and their partners in high-risk areas. In a similar screening program done during evening hours in Philadelphia, three residential sites and a soup kitchen were used. Among the 268 persons screened, 12 (4.5%) had untreated early syphilis (M. Goldberg, written communication, 1990). In a daytime outreach program conducted at recreation centers, development agencies, and a food give-away center in Rochester, NY, 205 persons were screened and only 1 (0.5%) had untreated early syphilis (T. Huntley, written communication, 1990). A high yield of cases may depend on identifying appropriate sites and times for the screening program. We believe the training of disease investigators, their experience in Chester, and their ability to establish rapport with persons in high-risk areas also contributed to the success of our program.

Our screening program was less costly per case treated than routine investigator activities in Chester during the same period. Our estimate of routine activity costs is probably low, because we excluded the cost of private treatment for routinely identified case-patients.

This program's impact on the outbreak is difficult to substantiate. The number of cases detected per week declined after our program, suggesting an effect on incidence. It is possible that cases identified during the screening program were identified earlier than they would have been otherwise, and all the program accomplished was earlier case-finding. If that is true, the program decreased the period of infectivity of case-patients and case contacts, which should reduce STD transmission.[21] The high percentage of early latent cases (which are asymptomatic) among our male case-patients also suggests that the screening program reduced transmission, because asymptomatic men account for a disproportionate share of STD transmission[21] and are unlikely to seek medical attention on their own.

Empiric on-site treatment was a new facet of our program. Such treatment "pits the clinical importance of accurate diagnosis against the policy of public health prevention." (p. 1081)[8] Fortunately, recommended treatment of early syphilis in most patients[11] is cheap, convenient, and has few major side effects. We found empiric treatment to be cost beneficial and well tolerated. We believe that providing such treatment for high-risk populations is safe, reaches persons who may not return for follow-up, and may reduce syphilis transmission.

The mobile van in this program proved to be an effective addition to a standing permanent structure. The usefulness of this strategy is influenced by proximity to a permanent clinic and availability of an adequate, reasonably priced mobile unit. Mobile units could also improve long-term contact between health workers and the community; however, our program did not evaluate the use of mobile units for this purpose.

Since treatment does not change underlying STD risk factors,(3) interventions of this kind cannot provide long-term disease control. For short-term reductions of syphilis incidence in outbreaks associated with cocaine and prostitution, however, an approach such as ours is recommended, especially the use of empiric first-visit treatment of persons recruited for screening. Consideration should be given to using such screening for longer periods, repeating the program in the same population at intervals to determine whether a change in incidence occurs, and adding other sites. If the case yield is high, screening programs should include empiric treatment or on-site RPR screening followed by immediate therapy. Only by using a variety of strategies can the best ones be selected to combat urban syphilis outbreaks. Prompt development of such strategies is important, particularly in light of the potential for human immunodeficiency virus spread among persons with ulcerous STDs.[22] ☐

Diverging Gonorrhea and Syphilis Trends in the 1980s: Are They Real?

Kenneth A. Gershman, MD, MPH, and Robert T. Rolfs, MD

ABSTRACT

Background. The purpose of this study was to evaluate whether the divergence in national trends of gonorrhea and syphilis from 1986 to 1989 in the United States was real and if overall trends masked a contemporaneous increase in both diseases in a core group.

Methods. We analyzed the following: (1) reported cases of gonorrhea and primary and secondary syphilis in the United States for the years 1981 to 1989, (2) gonorrhea screening results from six states for the years 1985 to 1989, and (3) reported cases of gonorrhea and primary and secondary syphilis by census tract for the years 1986 to 1989 in one city.

Results. The incidence of gonorrhea decreased 22% in the United States from 1986 to 1989 while the incidence of primary and secondary syphilis increased 59%. Among Blacks, syphilis incidence increased 100% and gonorrhea incidence decreased 13%; among Whites and Hispanics, the incidence of both diseases decreased. Results from gonorrhea screening among females in six states agree with gonorrhea incidence trends in those areas. Race-specific and census tract analyses of data from a number of metropolitan areas where overall rates diverged did not demonstrate a group in which the incidence of both diseases increased.

Conclusions. We conclude that diverging trends of gonorrhea and syphilis from 1986 to 1989 are real and emphasize differences in the epidemiologic characteristics of these two sexually transmitted diseases. (*Am J Public Health*. 1991;81:1263–1267)

Introduction

Declines in numbers of reported cases of gonorrhea and syphilis in the first half of the 1980s suggested that Americans had changed their sexual behavior in response to the AIDS epidemic.[1–3] Since 1986, however, syphilis incidence has increased[4] while gonorrhea incidence has continued to decline.

The recent spread of syphilis has been associated with drug use, especially cocaine.[5–8] Drug use has also been associated with the spread of gonorrhea, but this association has been less extensively studied.[9–11] Since syphilis and gonorrhea are transmitted in the same way, an increase in gonorrhea incidence, rather than a decrease, might be expected during the time when syphilis incidence increased.

The decrease in gonorrhea incidence, although probably real, could be the result of decreased surveillance and case detection activities. Anecdotally, reductions have occurred in sexually transmitted disease (STD) clinic visits in some cities and in gonorrhea screening programs in many states. Such decreases in gonorrhea case detection activities could result in artifactual declines in gonorrhea incidence. Alternatively, an overall gonorrhea decrease might mask an increase in the same core group in which syphilis has increased. To better understand if the divergence in national trends of gonorrhea and syphilis is real and whether this divergence masks a contemporaneous increase in both diseases in a subgroup of the population, we analyzed several types of data. These included (1) reported cases of gonorrhea and primary and secondary (PS) syphilis for the years 1981 to 1989, (2) gonorrhea screening results from six states for the years 1985 to 1989, and (3) reported cases of gonorrhea and PS syphilis by census tract for the years 1986 to 1989 in a city experiencing a large increase in syphilis.

Methods

We used summary data from 1981 to 1989 on cases of gonorrhea and PS syphilis reported to state health departments and sent annually to the Centers for Disease Control (CDC). Annual reports included summary data by gender, racial or ethnic group, age group, and source of report (public, private, or military) for each state and six large cities (Baltimore, Chicago, Los Angeles, New York City, Philadelphia, and San Francisco). Cases reported from public and private sources were combined; military cases were not included in these analyses. Racial or ethnic group was categorized as Black (not of Hispanic origin), White (not of Hispanic origin), Hispanic, Asian or Pacific Islander, or American Indian or Alaska Native.

Incidence rates for the United States were calculated using US Bureau of the Census population estimates for 1981–1989.[12,13] Estimates of the White and Black Hispanic populations were subtracted from estimates of Whites and Blacks to calculate estimates for Whites not of Hispanic origin and Blacks not of Hispanic origin.

Five states and two cities in 1983 and two states and three cities in 1984 did not

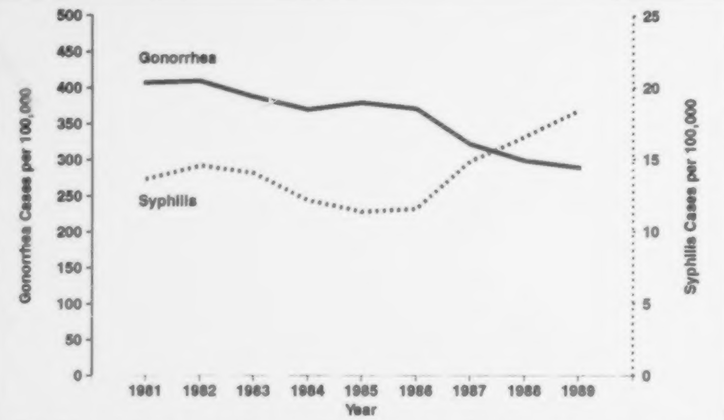

FIGURE 1—Trends in incidence of gonorrhea and primary and secondary syphilis, United States, 1981–1989.

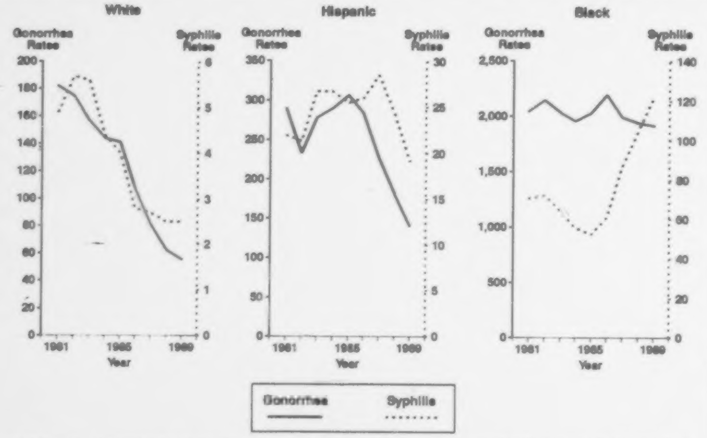

FIGURE 2—Trends in race-specific incidence of gonorrhea and primary and secondary syphilis, United States, 1981–1989. Rates = No. of cases per 100 000 persons.

submit annual reports of gonorrhea cases to CDC. Estimates for these areas were projected by averaging the sex and race distributions of cases in each area from the years before and after the missing year(s). Similar methods for interpolating missing syphilis data have been described previously.[4]

The proportion of gonorrhea cases reported with race not specified varied from year to year (17–19% for the years 1981 and 1986–1989 and 22–26% for 1982 through 1985). No cases were reported with sex not specified. Cases with race not specified were prorated to the race and sex distribution of known cases. To assess the validity of prorating, we tested varying assumptions, including the extreme assumptions that unspecified cases were all Black or all White. Gonorrhea trends were not sensitive to these extremes. Similar methods for prorating cases of syphilis with race not specified have been previously described.[4]

For the analysis of state trends, an increase in syphilis incidence was defined as a greater than 33% rate increase from 1986 to 1989 with both 1988 and 1989 rates higher than the 1986 rate. Only states with at lease 25 PS syphilis cases in 1989 were included.

Results of gonorrhea screening in women for the years 1985 to 1989 were obtained from six state STD programs where these data were available. The numbers of gonorrhea cultures performed and the numbers positive by type of facility were reported. STD clinic results were excluded and overall annual positivity rates (percent positive) were calculated for all other sources combined.

Cases of gonorrhea and PS syphilis by census tract for Rochester, NY, for the years 1986 to 1989 were obtained from the New York State STD program. Rochester was selected because gonorrhea and syphilis trends diverged there and census tract data were available. Census tracts were ranked by the number of PS syphilis cases reported in 1989. Core syphilis census tracts were defined as those with the highest ranking that cumulatively accounted for approximately 50% of cases.[14] Incidence rates were calculated using 1980 US Bureau of the Census population estimates by census tract.[15]

Results

National Trends

The incidence of both gonorrhea and syphilis decreased in the United States from 1981 to 1985 (Figure 1). From 1986 to 1989, the incidence of gonorrhea decreased 22% from a rate of 370.8 to 289.1 cases per 100 000 persons. The incidence of PS syphilis, however, increased 59% from a rate of 11.6 to 18.4 cases per 100 000 persons.

Among Whites, the incidence of gonorrhea decreased 48% from 1986 to 1989 (107.1 to 56.4 cases per 100 000), while that of syphilis decreased 11% (2.8 to 2.5 cases per 100 000) (Figure 2). Among Hispanics, the incidence of gonorrhea decreased 50% during this time (283.5 to 140.9 cases per 100 000) and syphilis incidence decreased 27% (26.0 to 19.1 cases per 100 000). However, among Blacks, a marked divergence in trends occurred: gonorrhea incidence decreased to a lesser extent than among the other groups, 13% (2197.1 to 1912.4 cases per 100 000), while syphilis incidence increased 100% (61.0 to 121.8 cases per 100 000). Sex-specific trends within each racial or ethnic group were generally similar to overall racial or ethnic trends. While syphilis incidence increased among White females from 1986 to 1989 (from 1.4 to 1.9 cases per 100 000 persons), their rates remained extremely low. Syphilis incidence among Hispanic females did not change appreciably during this time period.

Only 18 states reflect the divergence in national trends of gonorrhea and syphilis from 1986 to 1989. Although gonorrhea incidence rates decreased or remained unchanged in 45 states, syphilis incidence rates increased in only 22 states. In 18 of these 22 states, gonorrhea incidence decreased or remained unchanged.

1989	3867	266	1099	38

[a] Incidence is cases per 100 000 persons; core census tracts are those with 56% of primary and secondary syphilis cases in 1989.

Gonorrhea Screening

To evaluate whether changes in surveillance methods or case detection may account for the decrease in gonorrhea incidence, we compared trends in screening positivity rates in women and reported cases of gonorrhea in six states in which syphilis has increased (Figure 3). Screening and reported case trends were quite similar between 1985 and 1989 in these states. In two states (Oregon, Washington), screening positivity rates and reported cases both declined throughout the period 1985 to 1989; in three states (Alabama, Delaware, Louisiana), both trends initially declined then increased in parallel; and in one state (Michigan), both trends remained relatively unchanged. For two of the six states, the numbers of women screened decreased by 5% or less from 1986 to 1989. In the other four states, the numbers of women screened declined by 15% to 51%.

Core hypothesis. To evaluate whether the overall divergence in trends of gonorrhea and syphilis masked a contemporaneous increase in both diseases in a core group, we first analyzed race-specific case totals for 1986–1989 from several metropolitan areas where these data were available. In four metropolitan areas (Seattle, Memphis, Charlotte, Los Angeles) with an overall divergence in trends, stratification by race did not identify a group in which the incidence of both gonorrhea and syphilis increased.

To further evaluate the core concept, we analyzed census tract data from one metropolitan area. In Rochester, NY, gonorrhea incidence remained relatively constant from 1986 to 1989 (12% increase), while syphilis incidence increased 11-fold. We compared gonorrhea and syphilis incidence rates in the census tracts with approximately 50% of the city's reported syphilis cases (the core area) in 1989 (Table 1). Core incidence rates for syphilis and gonorrhea were 7.0 and 3.5 times higher, respectively, than noncore rates in 1989. Even in the core syphilis census tracts, however, trends for the two diseases diverged as syphilis incidence rates increased 24-fold, while gonorrhea incidence rates showed little change. A similar divergence, but of lesser magnitude, also occurred in the noncore census tracts. Of note, gonorrhea incidence rates for Rochester in 1987 were substantially lower than rates for all other years from 1984 to 1989.

Discussion

From 1986 to 1989, national trends of gonorrhea and syphilis incidence diverged: gonorrhea declined while syphilis increased markedly. This divergence occurred among Blacks, but not among Whites or Hispanics. Results from gonorrhea screening among females in a number of states support the overall decrease in gonorrhea incidence as real, rather than the result of changes in surveillance. We were unable to demonstrate a core group in which the incidence of both gonorrhea and syphilis increased.

Gonorrhea screening positivity rates declined from 1985 to 1989 in five of the six states we assessed, as did gonorrhea incidence. In the sixth state, both gonorrhea screening and incidence trends changed little. Screening positivity rates should be a reliable indicator of gonorrhea prevalence if the population screened remains relatively constant over time. For the two states in which the numbers of women screened changed little, parallel decreases in both screening and incidence trends strongly suggest that a real decrease in gonorrhea incidence occurred. In the other four states, however, the numbers of women screened decreased substantially from 1985 to 1989. Declines in screening positivity rates in these states may reflect real decreases in gonorrhea prevalence or may be the result of screening fewer high-risk women. Since STD programs are likely to reduce screening at clinics with the lowest yield and maintain screening among high-risk groups, these trends probably reflect true decreases in gonorrhea incidence.

Geographic clustering of both gonorrhea and syphilis cases among "core" census tracts in urban areas has been demonstrated previously.[14,16,17] Differential

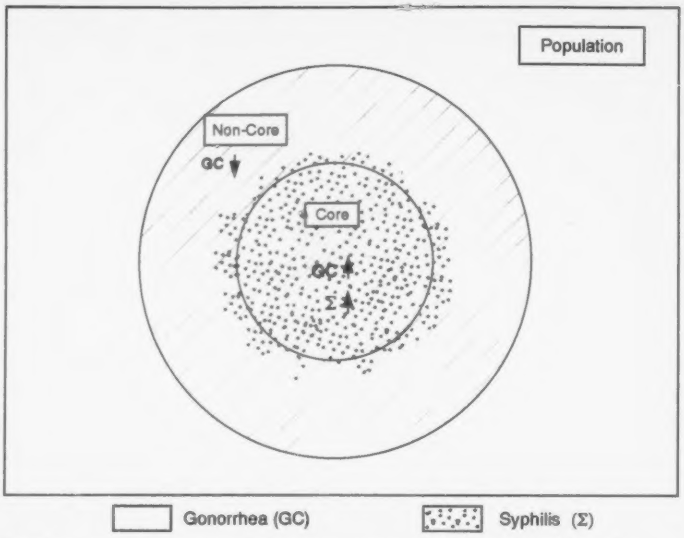

FIGURE 4—Core model of distribution of gonorrhea and syphilis in a metropolitan area.

changes in disease transmission for core and noncore groups might mask trends in the smaller core group (Figure 4). For example, the exchange of sex for money or drugs in a core group might lead to increases in both gonorrhea and syphilis incidence. Screening plus condom use or other behavior change, however, might decrease gonorrhea incidence in the much larger noncore group and mask the core group increase. Because the distribution of syphilis is largely confined to a core group, overall syphilis trends would be those of the core group.

If transmission of both infections increased in the core group while decreasing in the general population (noncore group), an overall decrease in gonorrhea incidence and increase in syphilis incidence would occur.

Neither the analysis of race-specific data in several urban areas with an overall divergence, nor the census tract analysis of another city demonstrated a group in which the incidence of both diseases increased. Race and geography are almost certainly not direct risk factors for STD; presumably they are surrogate markers for behavioral factors, which if better defined and measured would allow us to more clearly identify the core group. Race and geography alone may be inadequate to define a core group in which the incidence of both gonorrhea and syphilis increased.

It seems likely, however, that transmission of *Neisseria gonorrhoeae* has not been affected to the same extent by whatever factors have increased the spread of syphilis. Several factors might account for differences in the epidemiologic patterns of gonorrhea and syphilis in the United States. First, gonorrhea and syphilis may have different core groups. Although studies suggest that the core group involved in the recent syphilis increase is the same as the crack-using population, less evidence exists that these two groups overlap with the gonorrhea core group.[18] Second, gonorrhea and syphilis may have the same core group, but the factors that have increased the spread of syphilis may not affect the spread of gonorrhea. Oral sex has been reported to be the most frequent type of sexual activity involved in the exchange of sex for crack[19] (S. K. Koester, Ph.D., November 1990, written communication), and oral sex might be more effective in spreading syphilis than gonorrhea. Transmission of pharyngeal gonococcal infection to sex partners is thought to be inefficient and relatively rare[20] and, therefore, would be unlikely to sustain gonorrhea spread. Third, differences in health care seeking behavior among those with gonorrhea and syphilis might also contribute to the divergence. Males with gonococcal urethritis tend to seek treatment shortly after the onset of symptoms.[21] Prompt treatment translates into a short infectious period and interrupted transmission. In contrast, a large proportion of persons with infectious syphilis do not seek medical attention despite signs and symptoms.[22] Crack use and related factors such as unemployment and poverty may contribute to delays in seeking health care among persons with syphilis.

From 1986 to 1989, gonorrhea and syphilis trends have diverged for Blacks, among whom syphilis has increased dramatically since 1986, but not for Whites or Hispanics. An understanding of why syphilis but not gonorrhea incidence has increased in this population will better define transmission dynamics of these two diseases and, therefore, contribute to more successful control strategies. ☐

Hopkins Announces New Vaccine Effective Against Life-Threatening Infection

Johns Hopkins School of Public Health researchers have proven a new Hib (Haemophilus influenzae type B) vaccine effective in preventing life-threatening infection in young children when administered at 2 and 4 months of age. The vaccine, called Hib-OMPC, was tested on Navajo children who, like some other Native American populations, are 10 to 50 times more susceptible to Hib-related disease than the general US population.

"The widespread use of Hib-OMPC vaccine could virtually eliminate *H influenzae* and its deadly effects in children around the world," said lead author Mathuram Santosham, MD, MPH, director of the Johns Hopkins Center for American Indian and Alaskan Native Health. The results of the trial are reported in the June 20 *New England Journal of Medicine*.

Infection with Hib—which is actually a bacterium, not a "flu" virus—strikes 20 000 children in the United States per year. In half the cases the infection develops into meningitis, a potentially fatal infection of tissues surrounding the brain and spinal cord. Five to 10 percent of the infected die; survivors often develop neurological disorders, including hearing loss, paralysis, and speech problems. In addition to being the leading cause of meningitis, Hib can cause pneumonia; blood poisoning; infections of the ears, joints, skin, and lining of the heart; and a potentially fatal throat infection.

"The incidence of Hib-related infection is extremely high in Native American children because this population has a lower antibody response to Hib vaccines than the general population. We learned these differences in a recent study on Apache children," Santosham said.

"Proving the efficacy of Hib-OMPC vaccine in this high-risk population should also predict its efficacy in other populations," he added.

With the help of Raymond Reid, MD, MPH, a Hopkins research associate who is a Navajo physician, and a number of other investigators, Santosham directed the double blind placebo-controlled clinical trial in 3486 Navajo infants from July 1988 to August 1990 in Whiteriver, Az. The Hib vaccine was shown to be effective in preventing *H influenzae* disease when two doses were administered at 2-month intervals beginning at 6 to 12 weeks of age. When given at this early age, a single dose protected infants for at least 2 months; two doses gave protection at least to the age of 18 months. After that, a booster can be given, but the Hopkins researchers believe that generally the child's immune system by then has matured sufficiently to fight the Hib organism.

"Early vaccination is vital to the success of Hib-OMPC," said Santosham.

"We proved that this is the only vaccine available today which can be safely administered to an infant only 6 weeks old," Santosham said, "and which provides protection beginning with the first dose."

The vaccine has been developed by Merck Sharp & Dohme, who supported the research.

A Multistate Outbreak of Hepatitis A Caused by the Consumption of Raw Oysters

Jean-Claude A. Desenclos, MD, Karl C. Klontz, MD, MPH, Michael H. Wilder, MD, MS, Omana V. Nainan, MS, Harold S. Margolis, MD, and Robert A. Gunn, MD, MPH

ABSTRACT

Background. **In August 1988 we investigated a multistate outbreak of hepatitis A caused by Panama City, Florida, raw oysters.**

Methods. **Cases of hepatitis A (HA) with onset in July–August 1988 were identified among persons who ate seafoods harvested in the coastal waters of Panama City, Florida. We conducted a case-control study, using eating companions of case-patients, and calculated attack rate (AR) per 1000 dozen raw oysters served. Enzyme immunoassay (EIA) and a polymerase chain reaction (PCR) technique were performed on samples of raw shellfish obtained from Panama City coastal waters.**

Results. **Sixty-one case-patients were identified in five states: Alabama (23), Georgia (18), Florida (18), Tennessee (1), and Hawaii (1). We found an increased risk of HA for raw oyster eaters (odds ratio = 24.0; 95% confidence interval = 5.4–215.0; $P < .001$). The AR of HA in seafood establishments was 1.9/1000 dozen raw oysters served. The EIA and PCR revealed HA virus antigen and nucleic acid in oysters from both unapproved and approved oyster beds, in confiscated illegally harvested oysters, and in scallops from an approved area.**

Conclusions. **The monitoring of coastal waters and the enforcement of shellfish harvesting regulations were not adequate to protect raw oyster consumers. More emphasis should be placed on increasing public awareness of health hazards associated with eating raw shellfish. (*Am J Public Health.* 1991;81:1268–1272)**

Introduction

The consumption of raw or undercooked shellfish has caused numerous outbreaks of bacterial and viral enteric diseases worldwide.[1–18] In the United States, outbreaks of hepatitis A (HA)[4–8] and of Norwalk gastroenteritis[15–17] caused by the consumption of raw shellfish have been reported regularly since 1962, and raw or undercooked clams or oysters were implicated as the most frequent vehicle of infection.[4–8,13–17] To prevent the occurrence of such outbreaks, many states have adopted regulations to prevent the harvesting and distribution of shellfish contaminated by human fecal pathogens.[19] However, these regulations have not prevented raw shellfish–borne outbreaks of HA[8] and Norwalk virus gastroenteritis.[16,17] These outbreaks were linked to shellfish by epidemiologic data; however, to our knowledge hepatitis A virus (HAV) has not been identified in implicated shellfish during outbreaks in the United States.

We describe a large multistate outbreak of HA caused by the consumption of Florida raw oysters. During this outbreak we were able to identify HAV in illegally harvested oysters that we believe were the source of infection, using an enzyme immunoassay (EIA) and in vitro nucleic acid amplification, a method potentially applicable to monitoring the microbiological suitability of shellfish intended for human consumption.

Methods

Background

In early August 1988, cases of HA were reported among Alabama patrons of Panama City, Florida, seafood restaurants and oyster bars. Panama City, located on the Gulf of Mexico, is surrounded by three bays (East, West, and North Bay) where shellfish, particularly oysters, grow naturally. Registered fishermen harvest oysters according to a management plan monitored by the Florida Department of Natural Resources. Oyster beds are classified as approved, conditionally approved, or prohibited for harvesting according to factors such as rainfall, water salinity, and water coliform counts. For 7 years before 1988, the bays surrounding Panama City were closed to oyster harvesting each year from June 1 to August 31. However, in 1988, summer harvesting was permitted in North Bay.

Epidemiologic Investigation

A case of HA was defined as a person who was IgM antibody positive to HAV, or who was diagnosed with HA by a physician during July or August 1988, and

who had attended a seafood event 10–50 days before symptom onset. Cases were ascertained by contacting neighboring states, all local Florida health departments, and Panama City hospitals and physicians, and through interviews with case-patients and managers of seafood establishments.

We conducted a case-control study in August 1988. All case-patients reached by telephone were included in the case group. The non-ill meal companions named by each patient (0 to 3 companions named per patient) were included in the control group if they did not develop any symptom of HA during the 10- to 50-day period following the seafood meal, if they did not report a past history of HA or jaundice, and if they had not received immune globulin during the previous 3 months. Serum specimens were not obtained to detect asymptomatic infection among controls. A standardized questionnaire was used for telephone interviews with cases and controls to ascertain health status and food consumption during the seafood event.

The direct and indirect costs of the outbreak were estimated from medical information obtained during the case-control study. Direct cost was calculated using mean routine medical fees at local hospitals; indirect cost was calculated at a mean salary of $100 per day of work lost.

To estimate attack rates (ARs) for oyster bar patrons, we reviewed oyster invoices and records in Panama City seafood establishments where patients had eaten. ARs were calculated per 1000 dozen raw oysters served by week and by establishment.

Crude odds ratios (OR) and 95% exact confidence intervals (CI)[20] were calculated for each food and exposure investigated. Statistical tests used included χ^2 with Yates correction, the two-tailed Fisher exact test, the χ^2 for trend, and the Student *t* test for continuous variables. When case-patients had eaten in more than one restaurant during the exposure period, the analysis of data was restricted to the restaurant which had reported other case(s) being exposed on the same day.

Environmental Investigation

We traced the origin of oysters by reviewing oyster bag tag numbers recorded by seafood establishments. Information on illegal oyster harvesting activities in Panama City coastal waters was obtained from the Florida Marine Patrol. Coliform count records from shellfish growing areas and at a sewage treatment plant (plant A) were reviewed. We inspected Panama City approved and unapproved oyster growing areas to search for sources of fecal pollution and collected samples of oysters and water from approved (North Bay) and two unapproved areas (Watson and Beatty Bayou), scallops from a scallop growing area (Shell Island), and sludge from another sewage treatment plant (plant B) located in Watson Bayou. We also obtained frozen raw oysters that had been illegally harvested in Watson Bayou in early August 1988 and confiscated by the Florida Marine Patrol.

Laboratory Investigation

Coliform counts were done on water and oyster meat samples using the three tube five dilution technique.[21] For the detection of HAV antigen and nucleic acid, individual shellfish (oysters and scallops) were removed from the shell; the digestive tract, mantle, and muscle were minced; and material from two specimens was pooled, homogenized in phosphate buffer saline + 0.1M ethylene diamine tetra acetate (EDTA), and clarified by centrifugation. Separate instruments were used to prevent cross-contamination of specimens. Supernatants of the homogenated shellfish were tested for HAV antigen using a previously described EIA.[22] HAV was quantitated from a standard curve prepared from cell culture–derived HAV, strain HAS-15,[23] and diluted in oyster meat homogenate supernatant fluid from oysters not implicated in an illness outbreak. Sludge samples from the sewage treatment plant were prepared as a 10% (w/v) suspension, sonicated, and clarified by centrifugation, and the supernatant was tested for HAV antigen.

Specimens (resuspended homogenate pellets, homogenate supernatant, and sludge) were tested for HAV-RNA by in vitro nucleic acid amplification using the polymerase chain reaction (PCR). HAV-RNA was obtained by immunocapture of virus with the capture antibody used in the HAV-Ag EIA[24] followed by heating at 900°C in reverse transcriptase buffer for 3–5 minutes. The oligonucleotide primer complementary to HAV-RNA was annealed at 90°C for 3 minutes, cooled on ice, and cDNA was synthesized at 42°C for 1 hour with 200 μmoles dNTP's, 5 units AMV reverse transcriptase, and RNAscin.[25] The second primer was added and HAV-cDNA was converted to double-stranded DNA and amplified with a heat stable (Taq) polymerase in a thermal cycler for 30 cycles (DNA Thermal cycler, Perkin-Elmer Cetus, Norwalk, Conn). Amplified nucleic acid products were analyzed by electrophoresis at 10 volts/cm on a horizontal gel (Hoefer Scientific Instruments, San Francisco, Calif) in a composite agarose gel of 3% NuSieve and 1% Sekem (FMC Bioproducts, Rockland, Md) prepared in Tris-borate-EDTA buffer containing 0.5 μg/ml ethidium bromide. DNA specific for the amplified region of the HAV genome was identified by hybridization using a 32P kinase-labeled oligonucleotide probe that was internal to the two limiting primers used in the PCR.[25]

Results

Epidemiologic Investigation

Sixty-one case-patients were identified; all but two had been tested and were IgM anti-HAV positive. Of 53 patients interviewed, all but 1 stopped working while ill and 17 (32%) were hospitalized (range = 2–21 days, median = 4 days). The duration of illness ranged from 7 to 49 days (median = 21 days), and the median number of visits to a physician while ill was four per patient (range = 1–13 visits). There were no deaths; seven secondary cases occurred among household contacts of case-patients. The total cost of the outbreak was approximately $200 000: $73 000 for direct costs, i.e., medical care and the outbreak investigation, and $130 000 for indirect costs associated with lost work days.

Illness onset ranged from July 4 to August 15 (Figure 1), the exposure period from June 3 to July 21, and the incubation period from 16 to 48 days (median = 29 days). Case-patients lived in Alabama (23 persons), Georgia (18), Florida (18), Tennessee (1) and Hawaii (1). Case-patients ate in seafood restaurants or oyster bars in Panama City (53 persons, 86.9%), in a restaurant in Alabama that served oysters harvested in Panama City (3; 4.9%), and at private family gatherings in Panama City (5; 8.2%). Age of patients ranged from 8 to 60 years (median age = 31 years), and 49 (80.3%) were male.

Fifty-three case-patients and 64 controls were enrolled in the case-control study. Cases tended to be younger than controls (mean age = 27.5 and 32.2 years, respectively; $P = .02$) and were more likely to be male (81 vs 39%; $P < .001$). The risk of HA was greater for patrons who ate raw oysters than for patrons who did not (OR = 24.0; $P < .001$) (Table 1) and increased with the number of raw oysters ingested (Table 2). Of the two case-patients who did not eat raw oysters, one ate baked oysters, and the other ate raw

scallops caught at Shell Island beach. No other food items were associated with illness (Table 1), and the number of raw oysters eaten (>12 vs <12) had no effect on incubation period (<30 days; 55% vs 48%; rate ratio [RR] = 1.1; P = .9), duration of illness (>20 days; 79% vs 74%; RR = 1.1; P = .9), or hospitalization rate (29% vs 33%; RR = 1.1; P = .9).

During the exposure period, the 11 Panama City establishments associated with cases served approximately 27 900 dozen raw oysters. The median amount served per week was 3500 dozen (range = 1950–4800) (Figure 2), and the median number served by each establishment was 1994 dozen (range = 1050–8230). The overall AR was 1.9 cases per 1000 dozen raw oysters served with a peak during the third week of June (Figure 2). ARs by establishment ranged from 0.1 to 18 cases per 1000 dozen raw oysters, and most case-patients (44/52; 84.6%) had eaten raw oysters in one of four restaurants (A–D, Table 3).

Environmental Investigation

Seafood establishments and private individuals purchased raw oysters from wholesalers who obtained most of their oysters from Panama City–registered fishermen. Panama City bays met the defined safety standards at the time they were opened. Information gained from the Florida Marine Patrol indicated that illegal oyster harvesting at night was common during the summer of 1988, particularly in Watson Bayou where bootleggers arrested in early August had obtained multiple bags that they sold directly to some restaurants and oyster bars in Panama City.

Inspection of Watson Bayou showed failing septic tanks, boat sewage disposal, and sewage treatment plant sludge in proximity to unapproved oyster beds. Review of coliform counts at the effluent outfall of sewage treatment plant A was high [>16 000 most probable number (MPN)] from March through April 1988 and again in July, but not during May and June. This plant discharged approximately 1 mile from Watson Bayou.

Laboratory Results

Coliform counts higher than the maximum allowed were found in the water of two unapproved beds, although the oyster meat of only one of the beds was abnormal, and no human fecal pollution was detectable in the approved areas (Table 4). One of the three oyster pairs from approved beds of North Bay, all four scallops obtained from Shell Island, two oyster pairs from one of the beds sampled in Watson Bayou, and Watson Bayou oysters confiscated from a bootlegger were positive for HAV antigen by the EIA. HAV-RNA was detected by PCR in all oyster samples positive for HAV antigen by EIA (Table 4). However, two oyster samples HAV antigen negative by EIA were positive for HAV-RNA by PCR including a sample from Beatty Bayou, which was unapproved, and a sample from North Bay approved oyster beds (Table 4). Suspensions of sludge obtained from the sewage treatment plant were negative for HAV antigen and for HAV-RNA by PCR.

Discussion

This oyster-borne outbreak of HA is the largest reported in the United States since the 1973 Louisiana outbreak that involved 263 cases.[8] Although all case-patients recovered from their illness, the economic burden of the outbreak was high.

The risk of illness increased with the number of raw oysters consumed, suggesting a dose-response effect. However, there was no relationship between the quantity of raw oysters consumed and the incubation period, the duration, or the severity of illness. These findings suggest that the number of oysters eaten increased the chance of eating an infectious oyster rather than increasing the amount of virus ingested, which has been shown to decrease the incubation period.[26]

Although the case-control study showed that males had a greater risk of HA, this association is probably related to the use of eating companions of case-patients as controls: Florida adult males are more likely to eat raw oysters than females (Florida Behavioral Risk Factor Survey, Department of Health and Rehabilitative Services, unpublished data, 1988) and therefore to develop oyster-borne HA. Thus, controls as meal companions of case-patients were more likely to be females (spouse or girl friend).

Although the environmental investigation was not successful in definitively identifying the origin and the distribution of the contaminated oysters, we believe that contaminated oysters illegally harvested from unapproved waters were responsible for the vast majority of cases. However, we cannot exclude the possibility that some cases may have been caused by contaminated oysters harvested from approved beds of North Bay because both EIA and PCR identified HAV in oysters sampled there. Nevertheless, several factors strongly suggest that this outbreak was the result of bootlegging. First, because North Bay is the most common source of raw oysters served in Panama City, the observation of higher ARs of HA in four establishments suggests that more contaminated oysters were sold in those four establishments than in the other establishments. Second, according to anecdotal reports, many oysters had been illegally harvested from Watson Bayou in June and July 1988 and sold to specific seafood establishments in Panama City. Third, HAV was identified in oysters obtained directly from Watson Bayou and in oysters confiscated from a person who was arrested for illegal harvesting there. We also believe that the opening of Panama City coastal waters to summer harvesting after 7 years of summer closure facilitated the sale of the locally bootlegged oysters.

The raw scallops, eaten by one case-patient not exposed to oysters, were harvested off Shell Island where scallops were also found to contain HAV. This area is approximately 5 miles downstream from Watson Bayou, and a common source of fecal pollution may explain the contamination of shellfish from both locations.[14,15,18,27]

In the past, the isolation of viral pathogens from shellfish implicated in disease outbreaks has been difficult.[27] The finding of HAV by immunoassay in oysters obtained from the various harvesting areas indicated high levels of contamination. Even in the approved areas, oyster and scallop samples were positive for HAV by either or both EIA and PCR, which suggests that contamination may have been more widespread than was originally suspected. Virus isolation by cell culture was not attempted because of the extreme difficulty in growing wild-type HAV from environmental samples.[28] While direct proof of infectivity of either HAV-antigen or HAV-RNA positive oysters was not obtained, the epidemiologic evidence for infectivity was substantial, and it has been shown that HAV remains viable for long periods of time in water.[28]

The application of rapid viral diagnostic methods (EIA or PCR) for the identification of HAV and presumably other viral pathogens in shellfish has the potential for assuring the quality of this raw food product. However, these methods must be verified by infectivity studies in cell cul-

ture or nonhuman primates. This outbreak points out the failures of current regulations in assuring the quality of raw shellfish because enforcement cannot effectively prevent illegal harvesting, and it suggests that even approved areas may be contaminated with HAV. Emphasis must be placed on increasing the public awareness of the health risks associated with the consumption of raw or undercooked shellfish. □

Bleach Programs for Preventing AIDS among IV Drug Users: Modeling the Impact of HIV Prevalence

Joanna E. Siegel, ScD, Milton C. Weinstein, PhD, and Harvey V. Fineberg, MD, PhD

ABSTRACT

Background. **The growing importance of drug use as a mode of HIV transmission has led to increased attention to AIDS prevention among intravenous drug users (IVDUs). This analysis examines the effectiveness of bleach distribution, a program to prevent HIV transmission via shared needles.**

Methods. **We used a Markov model to assess the role of the initial HIV prevalence among drug users in determining the effectiveness of bleach programs. The model incorporates survey data on risk behaviors and published information describing HIV incubation and mortality. It predicts life expectancy for cohorts of IVDUs with and without a bleach program to estimate program effectiveness.**

Results. **We found that bleach programs can produce the greatest life-year savings in areas of low HIV prevalence. In the lowest prevalence scenario (0.02 initial prevalence), initiation of the program resulted in a projected savings of 2.3 life years per HIV-negative drug user, compared with 1.7 and 1.3 years under medium (0.25) and high (0.60) prevalence, respectively.**

Conclusions. **While bleach programs are beneficial in all groups of IVDUs, these results highlight the advantages of introducing bleach programs early, when prevalence is still comparatively low in a drug-user population. (*Am J Public Health.* 1991;81:1273–1279)**

Introduction

The proportion of AIDS cases occurring among persons whose primary risk factor is intravenous drug use has increased steadily since the beginning of the AIDS epidemic. In 1986, drug use was the primary risk factor for 16.8% of reported AIDS cases, compared to 21.5% currently.[1,2] Among new cases, the proportion is even higher.

Intravenous drug users (IVDUs) risk HIV infection from sexual contact and from sharing injection equipment—needles, syringes, or other items—with infected individuals. While protective changes in behavior have been reported among homosexuals, most IVDUs continue to place themselves at risk.[3,4] The growing importance of drug use as a mode of HIV transmission has increased attention to AIDS prevention in IVDU communities.

This analysis used a mathematical model to explore the effectiveness of one type of intervention, bleach distribution, for preventing AIDS among IVDUs. Bleach programs employ outreach workers to distribute small bottles of bleach, which IVDUs use to disinfect their injection equipment.[5] An important argument for the implementation of bleach programs in the United States has been that they are more politically feasible than needle exchange programs. However, arguments have been made for their use even where needle exchange programs are well established.[6]

Our study addressed the targeting of bleach programs, asking whether and to what extent initial HIV prevalence among IVDUs influences program effectiveness. A variety of obstacles, such as the difficulties of conducting longitudinal surveys of transient IVDU populations, prevent studies of existing programs from readily answering this question. Modeling therefore provides a practical means for studying the conditions that determine the success of bleach programs.

Methods

The model we used to predict bleach program effectiveness is a Markov (state-transition) model[7] similar to others developed to simulate the AIDS epidemic.[8-12] The model has four general states describing a hypothetical cohort of IVDUs (Figure 1). All IVDUs begin in an HIV-negative state. During each 1-year period, they face a risk of acquiring HIV infection from a needle-sharing partner and moving to HIV-positive status. Once infected, they face an annual probability of developing AIDS and then of dying from AIDS. HIV-negative and HIV-positive IVDUs die of other causes during the simulation. Death from non-AIDS causes is assumed to be negligible once an IVDU has developed AIDS.

We estimated probabilities of transition between model states from the literature, as described below. The model allows for recruitment of new HIV-negative drug users into the drug-using population. It also includes already HIV-positive

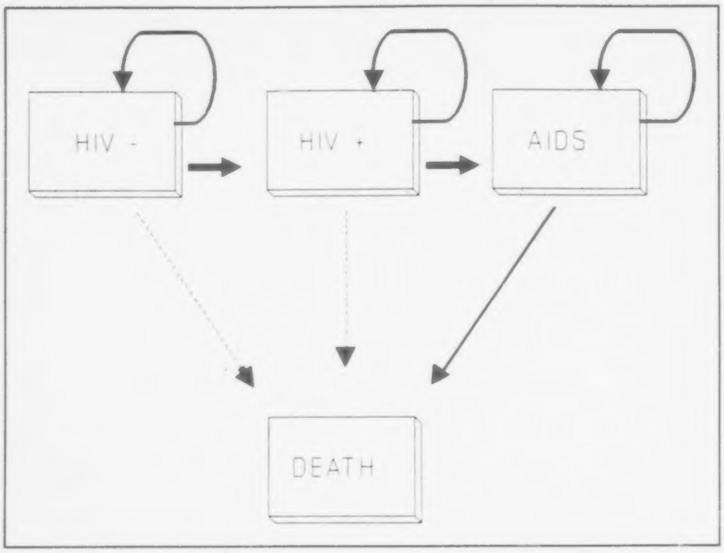

FIGURE 1—Markov Model of HIV transmission among Intravenous Drug Users.

IVDUs, who contribute to the prevalence of HIV in the community. Program effectiveness is calculated only for the initially HIV-negative IVDU cohort, however, and not for the community as a whole.

We use two measures of program effectiveness. The first, median infection-free survival, is the number of years until half of the modeled cohort become infected. The second is life expectancy, the average survival of cohort members.[7] Both measures capture the protective effect of bleach use on the individual IVDU as well as the reduction in HIV prevalence which protects other cohort members. Both also reflect continuing exposure to HIV—the fact that an IVDU who escapes infection for 1 year will be exposed again the following year. This long-term risk significantly increases lifetime probabilities of infection and is an important determinant of the effectiveness of interventions in an IVDU population.

Median infection-free survival and life expectancy are predicted both without and with a bleach program; effectiveness is defined as the improvement in these measures resulting from the program. We compared predicted effectiveness assuming programs are imple[illegible] where the HIV prevalence among drug users is low, medium, and high.

The analysis was conducted in three steps described in the results section: validation, baseline analysis, and sensitivity analysis. Change in life expectancy rather than median infection-free survival is used in the sensitivity analysis because its calculation is more precise. Computing is done on an IBM personal computer using the SMLTREE program (James P. Hollenberg, Copyright © 1985).

This model does not consider sexual transmission either within or outside of the drug-using population. While sexual transmission between individuals who also share needles is probably a secondary source of infection, sexual transmission to nondrug users is an important policy concern not directly addressed by our analysis.

Transition Probabilities

Risk of HIV infection. The cumulative annual probability of infection for IVDUs in the model depends on both personal behaviors and factors external to the IVDU (Appendix A). The risk behaviors include number of needle-sharing partners (m), injection frequency (i), and frequency of needle-sharing (s). The HIV prevalence among drug users in the community determines the probability of selecting an infected injection partner (p). A final component of risk is the probability (e) that the virus is transmitted when an IVDU shares injection equipment with an infected person. This probability is decreased when IVDUs disinfect their equipment with bleach (u,k). The model assumes that the risk of infection from each shared-needle contact with a given partner is constant and independent of previous contacts.

We used data from the Urban Health Study, a survey of IVDUs in San Francisco, to estimate drug-use behaviors.[13] From a sample of 603 interviewed in 1988, we selected those who reported both injecting drugs and sharing equipment during the previous year (n=251). The IVDUs we modeled were thus an active and at-risk subgroup of drug users.

Epidemic models suggest that heterogeneity of risk behavior may have an important effect on the course of the AIDS epidemic.[14,15] We considered heterogeneity among drug users by defining three separate groups at risk of infection. The groups are distinguished by frequency of injection (i), a behavior found to be associated with HIV infection, as our model specifies (Appendix A).[16–18] We used a partitioning algorithm, which minimizes total within-group variation, to differentiate groups within the Urban Health Study data. The resulting groups included a large number of "low-injector" IVDUs (≈1 injection per day); a "medium" group (≈4 injections per day); and a small "high" group (≈8 injections per day) (Appendix B). We determined the average proportion of injections shared (s) and number of needle-sharing partners (m) for each subgroup directly from the data.

Because injection frequency is associated with HIV infection, we assumed that the IVDU subgroups have different HIV prevalences prior to the bleach intervention (Appendix B).[16] In the course of the simulation, prevalence continued to be determined separately for the three groups. IVDUs in the model thus face a different annual probability of infection depending on their injection practices.

We estimated the probability of viral transmission per infected needle contact (e) based on the transmission in needlestick accidents among health care workers. Combining data from a number of studies, Friedland and Klein estimate a risk between 0.0013 and 0.0039 (upper confidence level = 0.0076).[19] We used 0.003 in our baseline analysis and, because this estimate is quite uncertain, a wide range was tested in the sensitivity analysis.

Bleach programs are actually multiservice outreach programs, referring IVDUs to treatment and providing information on risk behaviors. While other advantages of bleach programs may pertain, our model considers only the direct impact of bleach use on survival. We assume bleach effectiveness (k) of 85%—despite the virtually complete inactivation of HIV shown in laboratory studies of bleach[20-22]—to reflect problems in actual usage. If IVDUs disinfect only their needles, for example, the virus may be transmitted by other shared equipment. The probability that the IVDU uses bleach at each injection (u) is based on studies of IVDUs in San Francisco: 0.10 before the implementation of a program and 0.55 after.[13,23,24]

Risk of developing AIDS. Our estimates of the incubation period (time from HIV infection until the onset of AIDS) are based on data from the San Francisco Clinic Cohort, a group of HIV-positive homosexual men, because no similar studies document incubation in IVDUs.[25,26] We derive annual probabilities of developing AIDS from a Weibull model fit to these data, as described by De Gruttola and colleagues.[27,28] The Weibull model allows the estimated annual risk of developing AIDS, given HIV infection, to increase with time. The Markov model is adapted to reflect these time-dependent probabilities.

Annual probability of death. Probabilities of death for IVDUs with AIDS are based on a study of 1- to 5-year survival by Rothenberg et al.[29] Advances in treatment may ultimately increase survival, although the recent improvements among homosexual men have not been documented among IVDUs.[30] The impact of future treatments will depend on whether longer survival is associated with extended drug use. Our model currently specifies that persons with AIDS transmit HIV for only 1 year. Our conclusions would not be affected by a longer duration of infectivity, because most of the infection in the cohort takes place before AIDS develops. However, predicted life expectancy would increase. For this reason, our estimates of life expectancy are appropriate only for comparative purposes within this analysis.

Age-specific mortality from non-AIDS causes is derived from the US life tables for males[31] and adjusted to reflect higher risks of death from overdose and violence associated with drug use.[32] Not included in these probabilities is a substantial increase in mortality coincident with the AIDS epidemic, believed to be HIV-related.[33] The effect of an additional component of excess mortality among HIV-positive IVDUs is tested in the sensitivity analyses.

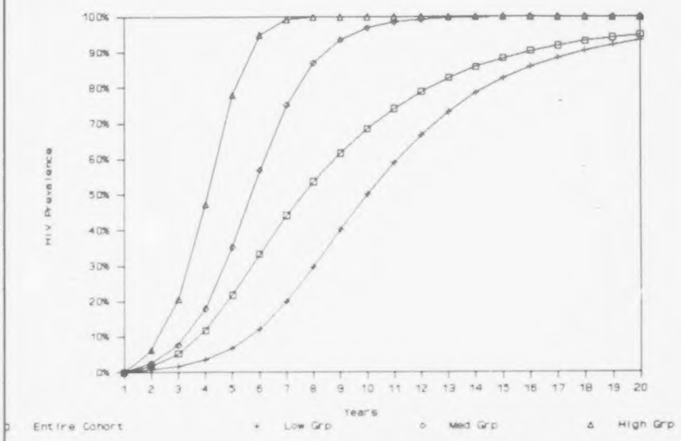

FIGURE 2—Increase in prevalence by risk group (initial prevalence 0.02).

Results

Validation: Model Dynamics and Predictions of Life Expectancy

One indicator of the validity of a model is that it obtains expected results under simple conditions. In this section, we examine how simulated life expectancy responds to variations and to extreme values of model parameters.

In the absence of AIDS, the model predicts an average undiscounted life expectancy of 26.64 years for a 35-year-old IVDU. For an IVDU who becomes infected with HIV at age 35, life expectancy is only 9.58 years. Life expectancy in the modeled cohort drops sharply when the virus is introduced, reflecting the rapid transmission of even low levels of HIV in this high-risk population.

The speed of dissemination of HIV in a drug-injecting population is illustrated by the increase in annual prevalence over time (Figure 2). When the initial HIV prevalence in the community is 2%, for example, cohort prevalence reaches 12% after 3 years and 53% after 7 years in the absence of an intervention program. (Community prevalence, which includes recruited IVDUs, is slightly lower.) This pattern of increasing annual prevalence falls within the range of trends observed in cities including New York, Edinburgh, and several Italian cities.[34-36] Prevalence increases are predictably slower among IVDUs who inject relatively infrequently and more rapid among frequent injectors.

Risk factors such as the number of injections per year (i) directly affect predicted life expectancy. Life expectancy decreases slightly at low levels of injection (Figure 3) and then more rapidly as infection becomes more probable. At high injection frequency, IVDUs are infected rapidly, and more frequent injection does not significantly worsen the risk.

While the results of these simulations are difficult to validate empirically, the model demonstrates plausible responses to changes in parameter values. Of note is the very rapid fall in life expectancy that occurs in response to modest increases in determinants of risk, such as HIV prevalence, injection frequency, or probability of viral transmission.

Baseline Estimates of Bleach Program Effectiveness

The baseline analysis examines the influence of HIV prevalence on predicted bleach program effectiveness, using our best estimates for parameter values. We compared effectiveness at three levels of overall initial HIV prevalence: low (0.02), medium (0.25), and high (0.60). These levels correspond to 1987 estimates of HIV prevalence among IVDUs in Los Angeles, Boston, and New York, respectively.[37,38]

The baseline simulations indicate that a bleach program would slow the epidemic most successfully in a low-prevalence area (Table 1). The median infection-free survival increases from 5.9 years

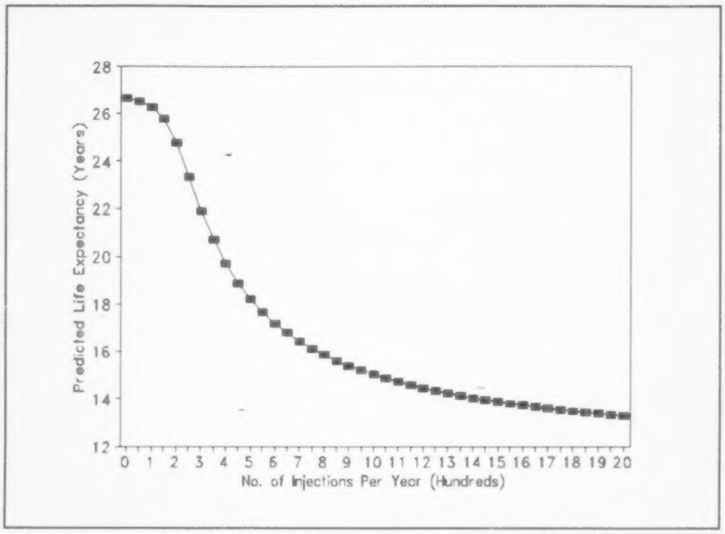

FIGURE 3—Predicted life expectancy by frequency of injection.

TABLE 1—Baseline Results for Low, Medium, and High Levels of Initial HIV Prevalence

Level	Initial Overall Prevalence[b]	Before Bleach Program	With Bleach Program	Change
Median infection-free survival, y[a]				
Low	0.02	5.9	8.6	2.7

TABLE 2—Gain in Life Expectancy Following Program Implementation: Sensitivity Analysis on Probability of Bleach Use

Initial Overall Prevalence	Probability of Bleach Use After Program Implemented			Complete Bleach Use and Bleach Effectiveness[b]
	55%[a]	90%	100%	
0.02	2.32	6.72	8.76	11.11
0.25	1.68	5.47	7.65	13.22
0.60	1.32	4.53	6.59	14.02

[a] Baseline value.
[b] At bleach use 100% and bleach effectiveness 100%, no further HIV infection occurs. This level of success is unlikely but illustrates the case when the greatest gain occurs in the high-prevalence scenario, where life expectancy was lowest prior to the program.

to 8.6 years. The bleach program also slows the spread of HIV in medium- and high-prevalence areas, but the change is less pronounced.

Predicted life expectancy demonstrates the same pattern of effectiveness. The bleach program adds more years to the life of an HIV-negative IVDU in a low-prevalence area than in a high-prevalence area. In the lowest-prevalence scenario, the initiation of the program results in a projected savings of 2.3 life years per HIV-negative IVDU (Table 1). The savings is 1.7 in the medium-prevalence area and 1.3 years under high prevalence. The program is thus predicted to be more effective in areas where drug users are less likely to be exposed to the virus.

Sensitivity of Results

Sensitivity analyses determine whether varying the conditions in an analysis will alter its conclusion. Changes in our model have the general effect of worsening or improving the predicted course of the AIDS epidemic. The question is therefore whether plausible changes in the predicted epidemic course would modify our basic conclusion, i.e., that bleach programs are more effective in low-prevalence areas.

Bleach use and effectiveness. Program effectiveness remains greatest in the low-prevalence scenario at any level of bleach use (u) (Table 2). This occurs because bleach effectiveness (k) is less than perfect, so that HIV infection continues even if IVDUs use bleach at all injections. Transmission is greatly slowed when both bleach use and bleach effectiveness are assumed to be higher. For example, with bleach used at 90% of injections and 95% effectiveness, median infection-free survival increases from 5.9 years without the program to over 20 years. However, combined bleach use and bleach effectiveness well over 90% would be required to change our baseline results.

Interactions among IVDUs. We examined annual recruitment of new drug users up to 10% of the original cohort size, the equivalent of, for example, an estimated 20 000 new IVDUs in New York City each year. (Table 3). Although the addition of larger numbers of uninfected IVDUs dampens the yearly increase in prevalence, higher program effectiveness is still found in the lowest prevalence area.

Sensitivity analysis on patterns of mixing among IVDU subgroups obtains a similar result. In the baseline analysis, we assumed a variant of "preferred mixing," in which IVDUs share most but not all injections within their own subgroup (Appendix B).[39] Sensitivity analyses test the effect of restricted mixing (sharing only with others in the same group) and proportional mixing (sharing unrelated to the user's own group). Effectiveness is generally higher with restricted mixing because the large low-injection subgroup is isolated from higher-prevalence IVDUs. However, overall effectiveness remains greatest at low prevalence regardless of the mixing assumption.

Components of risk: Probability of viral transmission (e) and injection frequency (i). In the sensitivity analysis on the per-injection probability of HIV transmission (e), predicted effectiveness remains highest in low-prevalence areas. However, at the lowest values of e (0.001), predicted effectiveness in low- and medium-prevalence areas is nearly the same. Effectiveness in this range of e has begun to diminish at the lowest prevalence level and would soon fall below that in medium- and high-prevalence areas. Therefore, while the baseline conclusion does not change in the sensitivity analysis, the illustration in Figure 4 reveals how still lower values of this parameter would change our results.

The sensitivity analysis on injection frequency also examines a lower risk scenario. Lower risk groups of injectors are defined by assuming five daily injections for any drug user reporting more than that number. The three risk groups are then recompiled using the method described previously. In this analysis, effectiveness increases at all prevalence areas and remains highest in the low-prevalence area.

Mortality. Although increased mortality from non-AIDS causes decreases life expectancy in our model, the pattern of program effectiveness is not changed. Effectiveness increases somewhat at all prevalence levels and remains highest at low prevalence.

Discussion

Under our best assumptions about the AIDS epidemic among drug users, we predicted that bleach programs would be most effective in low HIV-prevalence areas. Bleach programs thus save more lives when IVDUs are less likely to be exposed to HIV. Intuitively, this occurs because IVDUs are more likely to avoid (or delay) infection in low-prevalence areas; they therefore gain more life years if bleach prevents infection at a particular point in time.

Sensitivity analyses suggest that our results are reasonably stable. Predicted effectiveness is highest in lower-prevalence areas, with two exceptions. If bleach use entirely or almost entirely eliminates HIV transmission, the program is most effective where loss of life was initially greatest—the higher-prevalence areas. Or, if HIV infection is initially extremely unlikely in the low-prevalence area, effectiveness becomes quite low because so few lives are endangered by the epidemic that bleach has few to save.

These are extreme cases, however. Generally, factors slowing the AIDS epidemic would increase, not decrease, the relative effectiveness of bleach distribution in low-prevalence areas. If IVDUs use bleach consistently and reduce risk in other ways, the combination will offer im-

TABLE 3—Gain in Life Expectancy Following Program Implementation: Sensitivity Analysis on Recruitment, Mixing, Viral Transmission, and Injection Frequency

Factors	Initial Overall Prevalence 0.02	0.25	0.60
Recruitment[a]			
No new entrants	2.11	1.52	1.22
Recruitment 5%[b]	2.32	1.68	1.32

0.005	1.59	1.08	0.82
Injection frequency			
Baseline[b] (max. 10/day)	2.32	1.68	1.32
Lower (max. 5/day)	2.72	1.83	1.45

[a] Recruitment is number of new HIV-negative IVDUs entering model each year as percentage of number in original HIV-negative cohort.

[b] Assumption in baseline analysis.

[c] Restricted mixing is sharing equipment only with others in the same injection-frequency group. In preferred mixing, medium- and high-injector groups share 15% of injections with a lower-risk group and remaining injections within their own group. Proportional mixing is sharing unrelated to the user's own group.

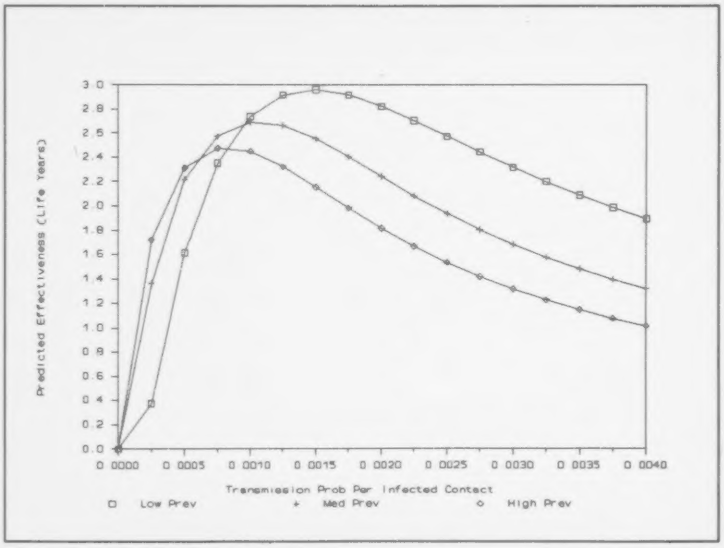

FIGURE 4—Predicted effectiveness by initial prevalence for assumptions of probability of HIV transmission per infected needle contact.

pressive life-saving potential, especially in low-prevalence areas (Table 2).

In the face of a dramatic and devastating illness such as AIDS, a reasonable response on the part of policymakers is to target resources to visibly distressed locations. What we wish to emphasize is the critical importance of preventive programs where AIDS may be less visible. It is in low-prevalence areas, before widespread infection has occurred, that bleach programs have their greatest potential for saving lives.

Several limitations should be considered before generalizing from the results of this model. There are limitations in the data, due to the intrinsic difficulty of surveying IVDUs.[40] Geographical differences in drug-use practices will affect generalizability. Some potential sources of heterogeneity have not been explored, for example, possible changes in viral infectivity over time. Our model does not reflect interruptions to drug use for periods of incarceration or drug treatment, which would lower the lifetime risk of contracting AIDS. These omissions will influence our predictions of life expectancy and may cause us to understate program benefits; they are less likely to affect our comparisons of program effectiveness across prevalence levels. As noted earlier, our analysis also excludes sexual transmission of HIV, a source of risk for IVDUs as well as their sexual partners and children. Nor are side-benefits of bleach distribution considered, such as education and referral to drug treatment.

In this analysis we have not assessed the cost or cost-effectiveness of programs in areas of differing HIV prevalence—and indeed the probable result of such an analysis is not obvious. However, because HIV prevalence among drug users can increase rapidly, our current opportunities for early intervention may be short-lived. The establishment of bleach programs in low-prevalence IVDU communities should become an explicit priority in a national effort to prevent AIDS. ☐

APPENDIX A—Risk of Infection for HIV-Negative Intravenous Drug Users[a]

$$r_j = 1 - [p((1-s_j e(1-uk))^{i_j/m_j} + (1-p)]^{m_j}$$

r_j = cumulative annual probability of infection
j = group of IVDUs
p = probability of selecting an infected injection partner (a function of prevalence in the several risk groups)[b]
s_j = probability that needle is shared; i.e., probability that someone used the needle immediately prior to this injection
e = efficiency of transmission of HIV by infected needle, per injection
u = probability that bleach is used at each injection[a]
k = effectiveness of bleach in eliminating HIV virus from a needle and syringe
m_j = number of partners per year
i_j = number of injections per year

[a] Further discussion in references 41–43.
[b] These parameters are group-specific in some model versions.

APPENDIX B—Model Specifications for Baseline and Sensitivity Analyses

	Baseline Analysis[a]			Sensitivity Analysis[b]		
Specification	IVDU			Subgroup		
Group-specific parameters	*Low*	*Medium*	*High*	*Low*	*Medium*	*High*
j Proportion of cohort in subgroup	0.60	0.31	0.09	0.43	0.35	0.22
i Number of injections per year	337	1311	3018	212	841	1723
s Fraction of injections shared	0.35	0.26	0.27	0.36	0.32	0.22
m Number of needle-sharing partners	11	13	12	10	14	11
p HIV prevalence among IVDUs						
Overall prevalence 0.02	0.012	0.031	0.031[c]	—	—	—
Overall prevalence 0.25	0.169	0.346	0.346[c]	—	—	—
Overall prevalence 0.60	0.478	0.704	0.704[c]	—	—	—
Cohort parameters						
u Per injection probability of using bleach						
Before bleach program implementation	0.10			—		
After bleach program implementation	0.55			0.56–1.00		
k Effectiveness of bleach	0.85			0.55–1.00		
e Probability of viral transmission per infected needle contact	0.003			0.001–0.005		
Other model features						
Mixing pattern among subgroups	Preferred[d]			Restricted; proportionate[e]		
Recruitment of new IVDUs into population (fraction of initial cohort population)	0.05			0.00–0.10		

[a] Values for group-specific parameters obtained from Urban Health Study data (see text).
[b] Sensitivity analysis on group-specific parameters assumes maximum of 1825 injections per year. Subgroups are redefined from data to obtain values of j, i, s, and m for sensitivity analysis (see text).
[c] Prevalences for medium- and high-injector subgroups assumed to be the same
[d]. Medium- and high-injector groups share 15% of injections with lower risk group and remaining injections within their own group.
[e] Restricted mixing is sharing equipment only with others in same injection-frequency group; proportional mixing is sharing unrelated to user's own group.

Inpatient Morbidity among HIV-Infected Male Soldiers prior to Their Diagnosis of HIV Infection

ABSTRACT

Background. A natural history study of human immunodeficiency virus (HIV) disease was carried out among 1575 HIV-infected US Army men and 6220 demographically similar uninfected soldiers. Inpatient morbidity occurring up to 8 years prior to the date of HIV infection diagnosis among those men who became HIV infected was evaluated for both groups.

Methods. Incidence density rates were calculated for hospital admissions. Poisson regression was used to assess the trend in hospital admissions among those subsequently diagnosed with HIV infection. Prevalence ratios for discharge diagnoses were also calculated.

Results. Sixteen diagnoses/diagnosis categories occurred statistically more frequently among subsequently HIV diagnosed individuals than among those who remained uninfected. Among these were hepatitis B and abscess of anal/rectal region (6 to 8 years prior to HIV infection diagnosis); unspecified viral infection, enlarged lymph nodes, syphilis (3 to 5 years prior to HIV infection diagnosis); and diagnoses suggestive of acute retroviral syndrome (1 to 2 years prior to HIV infection diagnosis).

Conclusions. Data such as these may provide useful information to HIV surveillance efforts regarding patterns of morbidity experienced prior to HIV infection as well as to health care providers regarding patients at high risk for becoming infected with HIV. (*Am J Public Health.* 1991;81:1280–1284)

Introduction

A natural history study of a large cohort of human immunodeficiency virus (HIV)-infected male soldiers and demographically similar uninfected soldiers was performed to investigate patterns of morbidity prior to and concurrent with early HIV infection. Hospital admission data during the period from HIV-infection diagnosis to 8 years prior to HIV diagnosis were analyzed to determine if the rate of hospital admissions differed for those later diagnosed with HIV infection compared to those who remained uninfected and if overall differences existed in the type and frequency of morbidity based on subsequent HIV-infection status.

Characterization of morbidity occurring around the time of HIV seroconversion is important for several reasons: (1) these signs and symptoms were not heretofore considered part of the clinical spectrum of HIV disease because they occur early in the clinical course, in some cases even before an individual suspects his or her HIV infection; (2) this information can be used by health care providers to assist in intervening early in the disease process; (3) it provides insight into the pathophysiologic processes that occur during the early stages of disease; and (4) it aids assessment of the burden and spectrum of morbidity that might be prevented by effective infection prevention programs.

Since October 1985, all military personnel on active duty and applicants for military service have undergone routine testing for HIV antibody (HIV-Ab).[1–4] Since the start of the screening program, the US Army HIV Data System (USAHDS) has archived the results of over 6 million HIV-Ab tests, approximately 2 million of them from active duty soldiers. The USAHDS maintains identifier-linked data files reflecting the dates and results of all HIV-Ab tests.

The US Army Medical Department also maintains a hospital discharge surveillance system called the Individual Patient Data System (IPDS). At the time of every discharge from an Army hospital, an entry is placed on IPDS consisting of demographic information, the primary discharge diagnosis and up to seven additional diagnoses, surgical procedures performed, and other medical care information. Thus, databases such as IPDS can be used to track hospitalized morbidity and medical care utilization over time for all beneficiaries of the Army health care system.

In addition to its ability to track morbidity among hospitalized cohorts, IPDS can be linked to other databases to track specific subcohorts of individuals. For example, when linked to the USAHDS registry of HIV seropositive individuals, IPDS provides a unique opportunity to evaluate the type and extent of inpatient morbidity in an otherwise healthy, employed HIV-infected population over an

−1	269	535	1575	6220	1.98 (1.72–2.29)

[a] CI = confidence interval.

Methods

HIV-infected male soldiers on the USAHDS registry with HIV-infection diagnosis dates between 1986 and 1988 were included in the study. The comparison group was composed of uninfected male soldiers identified from US Army personnel data bases. Four uninfected soldiers were matched to each infected soldier on the basis of age (±2 years), race (White, non-Hispanic; Black, non-Hispanic; Hispanic; Asian; other), rank (junior enlisted; senior enlisted; warrant officer; commissioned officer), and length of military service (±5 years). The file of study subjects was linked by social security number to the IPDS for retrieval of ICD-9-CM coded discharge diagnoses. A reference date (RD) was defined for each HIV-infected individual as the earlier of the date of his first confirmed positive HIV-Ab test or the date of any hospital admission specifically coded for AIDS or HIV infection. Uninfected soldiers were assigned the same RD as the HIV-infected soldier to whom they were matched.

Hospital admissions for each individual were allocated to the year in which they occurred relative to the RD. Due to the small numbers of admissions occurring more than 8 years prior to the RD, only those that occurred from 1 to 8 years prior to the RD were used in the analysis. To eliminate bias resulting from individuals with many hospitalizations, one admission per individual per year was used in the analysis. Similarly, duplicate diagnoses in the same year were eliminated, resulting in the occurrence of any specific diagnosis only once per person per year.

Statistical Analysis

For this analysis, HIV-Ab status was considered to be a marker for past exposures that resulted in hospitalizations. Because we were interested in determining whether the hospitalization pattern of HIV-infected individuals differed from the pattern of individuals not infected prior to the infected individuals being diagnosed with HIV, we selected the outcomes of interest to be hospital admissions and unique discharge diagnoses/diagnosis types.

Hospital admission incidence rates were calculated as time-specific incidence densities (ID) and defined as the number of new admissions per 100 person-years available in each year prior to the RD. The measure of association was the incidence density ratio (IDR) calculated by the formula $IDR = ID_1/ID_2$, where subscripts indicate demographic and time-specific strata. The Poisson method and a completely categorical model allowed for the calculation of the number of hospital admissions per stratum weighted by the follow-up time (p^*y) in each stratum, adjusted for age, race, and marital status.[5] Model fits were performed with the EGRET statistical package.[6] Ninety-five percent confidence intervals were calculated using the standard errors of β_k. The temporal trend associated with hospital admission incidence density ratios was determined over the 8 years prior to HIV infection diagnosis. The linear trend statistic calculated was the Poisson regression coefficient.

Prevalences (P) for unique discharge diagnoses, defined as the number of unique diagnoses of a particular type divided by the total number of diagnoses for both the HIV-infected and uninfected groups, were calculated over the combined 8-year period. Prevalence ratios (PR) for each unique discharge diagnosis defined as $PR_1 = P_{1(HIV\text{-}Ab+)}/P_{1(HIV\text{-}Ab-)}$, where subscripts indicate unique diagnosis types, were calculated for the combined 8-year period. Ninety-five percent confidence intervals were calculated using Taylor Series approximations.[7]

Results

A total of 1575 HIV-infected soldiers and 6220 uninfected soldiers were included in the study. The mean age for all subjects was 28 years. Thirty-four percent of subjects were White, non-Hispanic; 54% were Black, non-Hispanic; and 7% were Hispanic.

Hospital Admissions

There were 4602 hospital admissions between the RD and 8 years prior for all individuals in the study, 1469 among HIV-Ab positives and 3133 among HIV-Ab negatives. After removal of duplicate admissions within each year interval, infected soldiers experienced 1029 hospital admissions while uninfected soldiers experienced 2285 hospital admissions. Table 1 presents the number of hospital admissions and available person-years for HIV-Ab positive and HIV-Ab negative individuals in each year prior to the RD.

Figure 1 presents hospital admission rates for both groups over the 8 years prior to the RD. In general, admission rates for HIV-infected soldiers displayed a monotonic increase beginning 6 years prior to HIV-infection diagnosis. In contrast, admission rates among uninfected soldiers were nearly invariant. In comparison to the combined rates during the period 6 to 8 years prior to the RD, annual hospital admission rates increased overall by 79% in HIV-infected and 34% in uninfected soldiers. Admission rates were significantly greater in all years among those who were subsequently diagnosed with HIV infection. Further, the excess in hospital admissions among those with HIV infection became greater as the RD was approached (regression coefficient t test = -0.071, $P < .001$).

Individual Diagnoses

There were 1903 and 3671 diagnoses among HIV-infected and uninfected men,

respectively. Among the infected men, 792 unique diagnoses were reported. Further analysis focused on only these diagnoses. Their frequencies ranged from 1 to 74 among infected men and from 0 to 189 among those uninfected. Of the 792 diagnoses, 120 (15%) had four or more occurrences among HIV-infected soldiers. Of these 120 conditions diagnosed four or more times, 79 (66%) were more frequent (PRs >1.0) among HIV-infected vs uninfected men. Of these, 21 diagnoses were nominally statistically more common among men later diagnosed with HIV infection and had PRs ≥2.0. Table 2 presents the PRs and 95% confidence intervals for these 21 diagnoses.

Table 3 presents a qualitative description of the major causes of morbidity among individuals in this study. Those diagnoses with elevated PRs in each of three time periods are shown. Two diagnoses, hepatitis B and abscess of the anal/rectal region, are more common over the entire 8-year follow-up period among individuals subsequently diagnosed with HIV infection. From 1 to 5 years prior to HIV diagnosis, conditions associated with increased risk of HIV infection (e.g., syphilis and sexually transmitted diseases [STDs] other than syphilis) and with early HIV disease (e.g., unspecified viral infection and enlargement of lymph nodes) are significantly more common. Finally, at 1 to 2 years prior to diagnosis, conditions possibly associated with acute retroviral syndrome (e.g., unexplained fever and mononucleosis) are seen more frequently.

Discussion

The AIDS epidemic was first recognized in the late 1970s and early 1980s when previously rare illnesses began to be reported among gay men in San Francisco and New York.[8,9] Since that time these illnesses have been found to be associated with late-stage HIV disease. The natural history of late-stage HIV disease has been well characterized.[10-12] However, there have been relatively few detailed characterizations of the early stages of HIV disease.

Current interest in early intervention in the HIV disease course has focused interest on its presymptomatic stages.[13,14] Recent work has shown the efficacy of antiviral and prophylactic therapeutic intervention.[15,16] Trials are underway to assess effects of therapies when given in early, asymptomatic stages of HIV disease. It is important to clearly understand the early natural history of this disease before therapies are made available for general use.

It is important to document the usual course of HIV disease for a number of reasons. First, the early course is often thought of as presymptomatic. Indeed, individuals in late stages of HIV disease are likely to have trouble recalling illnesses that occurred years earlier. Furthermore, when a diagnosis is made early in the clinical course, interventions are applied that are specifically meant to delay or prevent the presentation of signs and symptoms. Medical surveillance databases that can document morbidity and HIV-infection status are not commonly available. Populations that are routinely screened for HIV and that have access to medical care in a single system are uncommon. Finally, it is difficult to determine whether morbidity that occurred years prior to a diagnosis of HIV disease was associated with the pathophysiology of HIV disease or was part of the background of morbidity of the base population.

In this study we investigated the natural history of HIV disease using routinely and systematically collected hospital admission records from members of a defined base population. This method allowed investigation of the period prior to the time of each individual's HIV-infection diagnosis. Thus, the "true" (albeit partial) natural course could be described among individuals not yet aware of and, therefore, not yet receiving care specifically for their HIV infection. Since this method does not rely on recall, it is also possible to assess HIV-related morbidity, as well as other types of morbidity, including that related to behaviors associated with HIV-infection risk. Finally, this approach provides insight into morbidity in relation to the experience of uninfected individuals from the same base population.

Our results indicate that hospitalization rates significantly increased among men who were subsequently diagnosed with HIV infection. This experience was in contrast to that of a referent group. During each of the 8 years prior to the date of initial HIV-infection diagnosis, men who became HIV infected experienced significantly higher rates of inpatient morbidity than men who did not.

This increase may be explained by (1) morbidity associated with acute HIV infection (e.g., fever, mononucleosis), (2) morbidity associated with progression of HIV disease through its clinical course, and (3) morbidity associated with behaviors that increase risk of HIV infection (e.g., STDs).

TABLE 3—Diagnoses with Elevated Prevalence Ratios (PRs) over Three Time Periods Prior to HIV-Infection Diagnosis.[a]

[a] Inclusion criteria for any diagnosis into the three time periods were the occurrence of that diagnosis (1) at least three times in 1 year or (2) at least two times in 2 or more years per time period among individuals later diagnosed with HIV infection.

Since exact dates of infection with HIV are unknown, the experience of the HIV-infected group cannot be further subdivided into pre- and post-HIV-infection periods. However, since HIV infection is irreversible and antibody to HIV is persistent, an "exposure gradient" can be used to characterize their experience: at the RD, 100% were infected with HIV (by definition); at an unknown time in the past, 0% were infected with HIV; in between there is a monotonic gradient of the proportion of the group with HIV infection. While at a particular point the proportion with HIV infection is not precisely known, the experience of the HIV-Ab positive group near the RD is more associated with HIV infection than any experience more remote.

Although small sample sizes for most diagnoses did not allow for year-specific analyses, we were able to observe some trends over the 8-year period. For example, lifestyle-related morbidity (e.g., STDs, anal/rectal trauma) declined as the RD was approached. It is possible that individuals diagnosed with HIV infection became aware of their risk and changed behaviors and partner selection practices prior to diagnosis. Decreasing STD rates from the early to late 1980s have been reported,[17–20] particularly among White homosexual men. These decreasing trends have been variously ascribed to heightened awareness of and fear of contracting HIV/AIDS. In this study, even at their lowest point (1–2 years prior to HIV-infection diagnosis) lifestyle-related diagnoses occurred nearly four times more often in men subsequently diagnosed with HIV. Current studies assessing risk factors for HIV infection in recently diagnosed soldiers[21] may shed light on the relationships of STDs and other lifestyle-related morbidity on risk of HIV infection.

Overall, the amount of substance use–related morbidity was not different between HIV-Ab positive and HIV-Ab negative individuals. Alcohol abuse or dependency accounted for approximately 50% of substance use–related diagnoses in both groups. The remaining morbidity was accounted for by opioid, cannabis, cocaine, barbiturate, hallucinogen, and unspecified drug abuse. Notably, there were eight opioid-dependency diagnoses among men diagnosed with HIV infection compared to none among other men. This suggests that intravenous—but perhaps not other—drug use was a factor in these infections. Studies of behaviors among recent HIV seroconverters[21] may provide insights into trends of intravenous drug use in relation to HIV infection in military populations.

St. Louis and colleagues[22,23] recently estimated community HIV prevalence based on seroprevalences among patients admitted to hospitals for non-HIV–associated diagnoses. They concluded that hospital patients in certain geographic areas of the United States should be routinely screened for HIV infection. The results of our study may be useful in broader settings to guide the clinical judgment of care providers regarding the potential risk of HIV infection among patients. A review of patient medical history and personal practices may refine assessments of risk, encourage HIV diagnoses, and focus counseling and health education efforts in routine medical practices. As a result, HIV-directed prevention/intervention programs aimed at early stages of HIV infection could have a significantly greater impact on decreasing morbidity and health care needs than just those interventions aimed at treatment and care of end-stage HIV disease (e.g., ARC, AIDS). Thus, communities may have sufficient reason to implement comprehensive prevention programs, the impact of which might be felt prior to the time when AIDS is clinically and epidemiologically apparent.

It should not be surprising that prior history of STDs, acute viral illnesses of unknown etiology, and hepatitis B were more frequent among men subsequently diagnosed with HIV infection than others. We suggest that these diagnoses should alert primary care providers of the increased risk of HIV infection, particularly in settings such as STD, emergency, and methadone maintenance clinics. Patients with sentinel diagnoses should be screened for HIV infection, counseled regarding risks of infection and transmission, and, if negative, actively followed for reevaluation. ☐

Utilization of Health Services in a Cohort of Intravenous Drug Users with Known HIV-1 Serostatus

ABSTRACT

Background. Intravenous drug users (IVDUs) with human immunodeficiency virus (HIV) infection and AIDS often have no health insurance or rely on public programs to finance their health care. We examined the independent contributions of HIV serostatus, clinical symptoms, CD4 cell counts, and health insurance to utilization of health services among 1881 intravenous drug users in Baltimore, Maryland.

Methods. Participants in an ongoing natural history study of HIV were informed of HIV serostatus and seropositives were informed of CD4 cell counts; 6 months later, participants were administered a questionnaire concerning self-reported use of health services, insurance coverage, and HIV-related symptoms.

Results. Of 1881 participants, 67% had health insurance (including Medicaid), 48% had at least one outpatient visit, and 12% had at least one inpatient visit within the prior 6 months. The proportion of the study population that was HIV-1 seropositive was 32%. In multivariate analysis, the single most important predictor of health care utilization was the presence of two or more HIV-related clinical symptoms. HIV positive serostatus alone or known low CD4 counts were not significantly associated with use of health care services.

Conclusions. These data suggest that HIV seropositive IVDUs are not receiving recommended preventive care. Additional efforts will be needed to ensure that HIV-seropositive drug users participate in currently recommended protocols for early treatment of asymptomatic HIV-1 infection. Introduction

By the end of January 1991, more than 161 000 cases of acquired immunodeficiency syndrome (AIDS) had been reported in the United States (K. Taylor, CDC AIDS monthly surveillance report, personal communication). Black and Hispanic adults account for a disproportionately large number of those infected.[1–5] The overrepresentation of minorities among those with HIV infection and AIDS is thought to be largely a consequence of intravenous (IV) drug use. It is estimated that IV drug use alone or IV drug use associated with homosexual or bisexual practices is responsible for 48% of the cumulative number of AIDS cases (K. Taylor, CDC, personal communication). One important outcome of the shifting demographics of the epidemic is that responsibility for financing and providing health care for people with human immunodeficiency virus type 1 (HIV-1) infection increasingly falls to the public sector.[6–9] Public policy will therefore play a significant role in influencing the availability of care, the timing of treatment, and the patterns of health service utilization. This research provides an initial examination of health services utilization among a population of IV drug users (IVDUs). Recent clinical research has demonstrated the important role of preventive care in delaying and mitigating the effects of opportunistic infections associated with HIV-1 disease.[10] Of concern is whether the recent advances in medical treatment, as well as the benefits of early clinical intervention, are available to the legions of IVDUs who comprise the second wave of the HIV epidemic.

The present study makes use of a data base available through an ongoing natural history study of HIV infection in IVDUs. The findings describe the relationship between health status and the utilization of medical services among IVDUs, as well as the role of health insurance in determining utilization patterns within this population.

Methods

Respondents to the health care utilization survey came from the AIDS Link to Intravenous Experience (ALIVE) Study, an ongoing longitudinal natural history study of HIV infection and IV drug use. ALIVE study participants were recruited through a number of strategies. Brochures describing the study were distributed to IVDUs who were being seen in agencies such as the Maryland Division of Parole and Probation, drug treatment programs, sexually transmitted disease clinics, emergency rooms, and homeless shelters. Also, participants were recruited via word-of-mouth. Eligibility criteria for the study included age of 18 years or older and a history of IV drug use in the previous 10 years. Individuals volunteering for the study were asked a series of questions concerning drug use history, incarcera-

tion, and history of homelessness in order to obscure the true eligibility requirements. Of the individuals who came to the study, 397 were disqualified because they did not admit to IV drug use. At entry into the study, 92% of the cohort demonstrated needle track marks on the extremity used for venipuncture. Participants reported a mean of 13 years of IV drug use at time of entry into the study. Forty-two percent of study participants reported a history of drug treatment within the previous 10 years and 13% reported a drug or alcohol treatment admission within the previous 6 months. The rationale and details of the data collection have been described in detail elsewhere.[11,12]

At the initial visit, after informed consent and pretest counseling procedures, trained interviewers administered a detailed questionnaire including sections on sociodemographic information, medical history, including symptoms associated with HIV disease (Appendix A), and current and past drug use and sexual practices.

All participants had blood drawn for HIV-1 antibodies. Specimens were determined to be positive if they were reactive on two ELISA tests (Genetic Systems, Seattle, Washington) and were confirmed with Western blot assay (DuPont, Wilmington, Delaware). All screening clinic participants were given AIDS risk reduction education and appointments to return to the clinic in 3 weeks to receive HIV test results. Participants were informed of the availability of a full-time addictions counselor on staff who would facilitate referrals for drug treatment. Study participants were able to see the addictions counselor on an immediate walk-in basis.

At the return visit, all seropositive individuals and a sample of 150 HIV-negative individuals were invited to participate in the follow-up clinic, which involved semiannual visits for behavioral interviews, physical exams, and venipuncture to assess CD4 counts.[13] All other study participants were invited to continue in the screening clinic, which consisted of semiannual HIV testing and interviews. At all points in the study, health was monitored, and HIV-positive individuals were given counseling and referred to the local HIV clinic for treatment or prophylaxis when indicated by symptoms or CD4 levels.

Beginning in December 1988, health care insurance and utilization questionnaires were administered to all individuals participating in the screening or follow-up components of the ALIVE study. The data presented below describe health care utilization, demographics, health status, and health insurance coverage of a group of 1881 study subjects. The validity of self-reports of insurance status was examined by comparing self-reported Medicaid coverage and Medicaid claim files on a subsample of the study population. An 88% agreement between self-reports and Medicaid files was found.

Statistical Analysis

Our analytic point of departure is a set of descriptions of the sample in terms of their use of health care services, HIV-1 serostatus, insurance coverage, and clinical symptoms. Two measures of severity of illness, presence of two or more AIDS-related symptoms, and CD4 levels were used. The selection of stratification levels for CD4 counts was chosen to conform to old and new guidelines for clinical services. Prior to 1990, a CD4 count <200 was used as an indication for initiation of prophylactic treatment with zidovudine,[9] whereas current practices call for the use of zidovudine when CD4 levels are <500.[14] Frequency distributions of variables by HIV-1 serostatus were compared using χ^2 statistics; continuous variables were compared by subgroups using analysis of variance.[15]

The independent impacts of service utilization on the three variables of primary interest were accomplished via estimation of a probit regression for two dichotomous dependent variables: whether or not any inpatient care was used by an individual during a 6-month period and whether or not any outpatient care was received during the same period. Obtaining unbiased estimates of the impact of insurance coverage on use of services is complicated because there may be unmeasured factors that determine both insurance coverage and service utilization, for example, the degree of concern with one's health. We used an instrumental variables estimation technique described by Maddala[16] to address this potential source of bias. The standard errors of the estimates for this two-stage instrumental variables model were calculated by following the procedure proposed by Amemiya.[17]

Results

Descriptive Findings

Table 1 presents sociodemographic features of participants in the health utilization study (N = 1881). This group was predominately male (79%), non-White (92%), of low socioeconomic status (income below $5000—73%), and had a median age of 34. The proportion of the study population that was HIV-1 seropositive was 32% (n = 610).

Table 2 shows the association between insurance in the 6 months prior to interview and HIV-1 antibody status. HIV serostatus was not significantly associated with the presence of any type of health insurance.

Table 3 shows comparisons for the number of inpatient and outpatient medical visits between HIV seropositive and seronegative individuals. HIV seropositive individuals averaged significantly more inpatient admissions (0.21) in 6 months compared to HIV seronegative individuals (0.13). No significant difference was observed in the mean number of outpatient medical visits or inpatient drug or alcohol admissions by HIV-1 serostatus.

The effect of severity of illness on health service utilization was examined via two separate measures of severity, CD4 levels and presence of two or more HIV-related symptoms. Table 4 shows comparisons between use of health services, CD4 counts, and HIV-related symptoms. The CD4 counts of HIV positive individuals were stratified into three groups—<200, 200–500, and >500—and the mean number of visits was compared to that observed in a group of HIV seronegative IVDUs. HIV seropositive individuals with CD4 counts <200 and those with counts of 200–500 were significantly more likely to use inpatient services than a comparison group of HIV negative drug users ($P < .021$ and P .033, respectively). HIV positive individuals with CD4 levels <200 had higher numbers of outpatient visits than the comparison group of HIV seronegative IVDUs ($P < .079$). There was no significant difference in number of outpatient visits noted between HIV seropositive individuals with CD4 counts >200 compared to number of visits of HIV seronegative individuals.

The effect of symptoms on utilization of health services is also presented in Table 4. The mean number of outpatient visits of HIV seronegative individuals was compared to both HIV seropositive individuals with zero or one symptom and HIV positive individuals with two or more AIDS-related symptoms. Those with two or more symptoms were found to have significantly more inpatient admissions and outpatient visits than HIV seronegative individuals ($P < .001$ and $P < .003$, respectively).

Table 5 shows the relationship between insurance coverage and utilization of medical services in the prior 6 months. All individuals with health insurance, regardless of their HIV serostatus, had significantly more inpatient admissions, outpatient visits, or drug or alcohol treatment admissions than those without health insurance. We also noted a significant relationship (not shown) between utilization of emergency rooms and absence of health insurance ($P < .001$).

Multivariate Findings

Table 6 presents estimates from the two-stage instrumental variables probit model. (Estimates from the first stage of the model are presented in Appendix B. The rationale for the instrumental model specification is presented in Appendix C.) We expected to find a positive correlation between HIV positive serostatus, older age, symptoms, and insurance with both inpatient and outpatient health service utilization. Only one measure of severity—presence of two or more AIDS-related symptoms—was entered into the model. This measure was chosen instead of CD4 counts because data were available for all study participants and CD4 counts of <200 were strongly cor-

related with the presence of two or more HIV-related symptoms. The first column of the model presents the results for the determinants of inpatient utilization, and the second column presents the results for outpatient utilization as a dichotomous variable. Although the results of the model for inpatient and outpatient are qualitatively similar for both models of utilization, there are some important differences. In terms of the variables of central concern, the results indicate that holding constant demographic factors and AIDS-related clinical markers, having insurance was marginally associated with the probability of inpatient care ($P <$ .06). However, insurance coverage has no significant impact on the use of outpatient care.

The variable representing HIV status was estimated to have a positive though not significant association with the probability of using either type of health care services. Although the coefficient estimate in the inpatient utilization model had a t statistic of 1.44, indicating a moderate amount of precision in the estimate, this was not significant by conventional standards. This suggests that holding constant demographic factors, insurance coverage, and symptoms, HIV serostatus did not have a significant independent impact on service utilization. Formal tests for interactions between HIV positive serostatus and the presence of health insurance showed no significant effects. As Table 6 shows, after adjusting for demographic variables, insurance, and HIV serostatus, the presence of two or more AIDS-related symptoms demonstrated the strongest association with the likelihood that an individual would get either inpatient or outpatient care.

Discussion

This study examined the relationship between health insurance, HIV-1 serostatus, and AIDS-related symptoms and the impact of these factors on the utilization of both outpatient and inpatient medical, drug, and alcohol treatment services. The presence of two or more AIDS-related symptoms had the strongest influence on the use of both inpatient and outpatient health care services. This is consistent with other research documenting the important role of symptoms and complaints in predicting service use.[18,19] In the multivariate analysis neither HIV-1 positive serostatus nor low CD4 levels in the absence of symptoms were associated with increased health services utilization. However, health insurance was significantly associated with the likelihood of using inpatient medical, drug, or alcohol treatment services. Even among individuals with low CD4 counts or AIDS-related symptoms, the absence of health insurance was associated with lower probabilities of receiving inpatient treatment. We did not find a significant relationship between the presence of health insurance and outpatient service utilization, which may be due in part to the availability of free care in East Baltimore. For example, the HIV clinics at certain local hospitals treat all individuals regardless of insurance status.

The next major finding is a negative one. Asymptomatic HIV seropositive subjects were estimated to be no more likely to use services than are HIV seronegative individuals. This is a particularly important problem because the greatest advances in treating HIV disease involve the postponement of manifestation of opportunistic infections that are the major causes of death in AIDS patients. Current medical practice recommends prophylactic treatment when CD4 counts drop below 500 mm^3, a level at which symptoms are not usually present. Failure to enroll HIV-positive individuals in health care prior to the appearance of symptoms suggests that preventive care, monitoring of CD4 counts, zidovudine prophylaxis, and prophylaxis for pneumocystis pneumonia are probably lacking and implies that individuals are not seeking care until they become very ill.

Programs to expand testing for HIV-1 in high-risk groups have been endorsed as an important element in promoting the early treatment of HIV-1 disease.[20] However, this study suggests that identification of HIV-1 positive status alone does not necessarily result in the initiation of preventive care. IVDUs often remain outside the health care system, using services on an emergent basis and frequenting emergency rooms rather than primary care clinics. Characteristics inherent in drug addiction (e.g., an overwhelming need to secure drugs daily) may make IVDUs particularly unable to conform to the requirements of many clinics for scheduled appointments and compliance with therapeutic plans. Efforts to encourage the early use of preventive services in this population will need to confront both the preferences and habits of the IV-drug-using population as well as institutional impediments to the use of services.[21,22]

Additionally, attention must be focused on making the drug-using community aware of the importance of early and continuous medical assessment and care. To date, education concerning HIV has focused on prevention of infection with implicit messages concerning the fatal consequences of HIV disease. Existing programs may have overlooked the need to provide information about the benefits of preventive treatment. Programs to expand medical services to drug treatment programs have become more common in Baltimore. Although this may increase knowledge and use of medical services to individuals participating in these drug treatment programs, our research suggests that the vast majority of drug users remain outside the drug treatment setting.

Conclusions based on this study may be limited by characteristics of the study population. This study reimbursed individuals for their participation; therefore, those with acute financial need may be overrepresented. Additionally, reports of insurance status as well as health services utilization were based on self-reports, the accuracy of which may be questionable. In spite of these potential limitations this study presents data on a cohort of drug users that are largely unaffiliated with a drug treatment program. Thus it may offer a more accurate picture of the use of services and the extent of care that many HIV seropositive drug users outside of treatment facilities are receiving. This study suggests that in spite of recommendations from the Centers for Disease Control for early treatment of HIV disease, many drug users still remain outside the health care system without benefit of preventive care. ☐

Acknowledgments

Portions of the preliminary data were presented at the 5th International Conference on AIDS in Montreal, Quebec, Canada (Abstract No. T.E.P.43).

This research was supported by the Agency for Health Policy and Research grant HS6411 and the National Institute on Drug Abuse grants DA04334 and DA05664.

We are grateful to Chuanfa Guo for his expert programming assistance and to the staff of the ALIVE study, without whom little of this work would have been possible. We also thank Dr. Joseph Margolick for his assistance with CD4 cell monitoring. Dr. Julia Hildalgo of the Maryland AIDS Administration gave invaluable assistance in verifying records.

APPENDIX C—Rationale for Instrumental Variables Model Specification

Within the model specification it is important to include at least some independent variables that are not included as part of the utilization model. While this is difficult to accomplish on a priori grounds, we choose two variables that relate to the price of insurance. This is consistent with sequential budgeting on the part of consumers. Under such arrangements consumers first make a choice regarding the purchase of insurance and then subsequently choose to buy other goods based on the remaining income. Under such a model, variables affecting the price of insurance will have little effect on utilization. The two variables that differ between the two models are whether or not individuals have children and whether or not they are employed. We posit that these variables have a strong impact on the likelihood of having insurance and little effect on utilization once income, demographic features, and health status are taken into account.

Risk Factors for Shooting Gallery Use and Cessation among Intravenous Drug Users

David D. Celentano, ScD, David Vlahov, PhD, Sylvia Cohn, MPH, James C. Anthony, PhD, Liza Solomon, DrPH, and Kenrad E. Nelson, MD

ABSTRACT

Background. Shooting galleries, locations where intravenous drug users (IVDUs) can rent or borrow needles and syringes, are a high-risk environment for HIV-1 transmission. This study investigates risk factors for lifetime attendance at shooting galleries and differentiates characteristics of those who continue to frequent shooting galleries and those who have stopped.

Methods. We interviewed 2615 active IVDUs in Baltimore in 1988 and 1989 and determined patterns of IV drug use, sociodemographics, and HIV-1 serostatus as related to persistence vs cessation of shooting gallery use.

Results. Over half (52%) of active IVDUs reported ever using a shooting gallery, with 33% reporting use within the prior 3 months. In multivariate analysis, lifetime shooting gallery use was associated with male gender, homosexuality/bisexuality, low socioeconomic status, Black race, and heavier drug involvement. Persistent shooting gallery users were more frequently male, homosexual/bisexual, homeless, less educated, and started IV drug use more recently compared with those who ceased going to shooting galleries.

Conclusions. Shooting gallery attendance may be pragmatic from a sociological and economic perspective, but it carries with it a heightened risk of acquiring HIV-1 infection. (*Am J Public Health*. 1991;81:1291–1295)

Introduction

Behaviors that increase the risk of infection with human immunodeficiency virus, type 1 (HIV-1) among intravenous drug users (IVDUs) are primarily those involving transfer of blood through shared injection equipment.[1-5] Use of shared equipment at shooting galleries is particularly high risk for acquiring HIV-1 infection.[6-8] Shooting galleries are locations, generally clandestine, where IVDUs can rent, borrow, or purchase needles and syringes; frequently the injection equipment is used repeatedly and may contain contaminated blood. Repeated rental of syringes results in a sequential anonymous sharing of potentially contaminated equipment. Such sharing facilitates the transmission of blood-borne pathogens.[1]

Although needle sharing has been empirically demonstrated to be one of the principal AIDS risk behaviors among IVDUs,[9,10] reports on the characteristics and behaviors of IVDUs who use shooting galleries are sparse. Ethnographic reports suggest that IVDUs go to shooting galleries for several reasons, including (1) the illegality of possession of drug injection equipment and consequent fears of arrest; (2) the scarcity of syringes, leading to an economic imperative to share injection equipment; and (3) the social context of intravenous drug use.[11,12] In this report, we used social survey methods on a large sample of currently active IVDUs to complement the findings from the published ethnographic reports to examine reasons for shooting gallery use and to identify reasons for cessation vs persistence in gallery use.

Methods

Sample

Between February 1988 and March 1989, IVDUs in Baltimore, Md, were recruited into a longitudinal investigation of the natural history of HIV-1 infection [the AIDS Links to the Intravenous Experience (ALIVE) Study]. Recruitment relied predominately on word-of-mouth by community outreach efforts (85%); referrals from drug abuse treatment programs, sexually transmitted disease clinics, local emergency departments, university hospital HIV-1/AIDS clinics, and shelters for the homeless also assisted with cohort recruitment. In order to be eligible for enrollment, IVDUs had to be age 18 or older and have self-reported illicit drug injection in the prior 10 years. The rationale and details of the sampling and data collection plan have been described elsewhere.[13]

A total of 2921 participants were enrolled in the ALIVE study and completed baseline interviews and venipuncture. In this analysis, we restricted the sample to the 2615 IVDUs who reported injecting illicit drugs within 6 months prior to interview.

Data Collection Procedures

After providing voluntary informed consent, participating IVDUs were assigned a unique and confidential identifier and agreed to venipuncture for serum for HIV-1 antibody assays. Next, participants were questioned by a trained interviewer in a private room concerning demographic information, medical history, drug injection practices since 1977 on an annual basis, 10-year history of sexual activity, knowledge and attitudes about HIV-1 infection and AIDS, and use of medical care. A detailed description of the data-gathering procedures appears elsewhere[14]; a brief overview is presented here.

The self-report demographic data analyzed here include age, gender and sexual orientation, race/ethnicity, education, current employment, receipt of public assistance, and occurrence of homelessness within the prior 10 years. Participants were asked to recall their drug use behavior in the 6 months prior to their last injection and also in the first 3 months of use. Drug injection frequency reported for the prior year was categorized as once or more a day or as less frequently. Other drug involvement factors analyzed included self-reports of treatment for drug abuse, being arrested and incarcerated within the prior 10 years, and duration of drug use as indicated by the year when drugs were first injected. Although there was a battery of questions on history of sexual practices, we restricted the analysis here to one indicator: whether any sexual partner was an IVDU.

We inquired as to the use of shooting galleries on an annual basis (thereby determining never and ever use) beginning in 1977 or year of first drug use. Recent shooting gallery attendance was ascertained as follows: "During the 6 months before the last time you injected drugs, how many times did you go to a shooting gallery and use works borrowed, rented, or bought there?" For the analyses here we aggregated the responses into three categories: never went to a shooting gallery, former shooting gallery user but no use in the prior 6 months, and current user of shooting galleries (i.e., attendance within the prior 6 months).

Analysis

To examine the associations of sociodemographic and drug use characteristics with attendance at shooting galleries, we cross-classified current, former, and never users of shooting galleries with the predictor characteristics, using χ^2 statistics as an aid to interpretation. The strength of associations between these characteristics and practices and shooting gallery attendance was estimated by the odds ratio (OR), using the group of IVDUs who reported never going to a shooting gallery as the reference category. Logistic regression was used to examine the simultaneous association of these factors to lifetime shooting gallery use (comparing ever vs never), as well as to identify factors associated with persistence of this risk behavior (comparing current and former users). We used 95% confidence intervals (CIs) as an aid to statistical interpretation of results.

Results

Of the 2615 IVDUs still injecting drugs enrolled in the ALIVE study, 32.9% (n=861) reported attendance at a shooting gallery within the prior 6 months, and 19.4% (n=507) reported having gone to a shooting gallery in the past but not within the prior 6 months. Slightly less than one half (47.7%; n=1247) of the respondents denied ever having injected drugs in a shooting gallery.

The relationships between the demographic and drug use characteristics and lifetime shooting gallery attendance are presented in Table 1. Those IVDUs who have ever used shooting galleries were more likely to be male, homosexual/bisexual, slightly older, Black, and unemployed, to have received public assistance, and to report being homeless sometime in the prior decade, as compared to IVDUs who reported never injecting drugs in a shooting gallery. A review of drug involvement factors shows shooting gallery attenders were more likely to report an arrest or incarceration history, to have been in drug treatment as compared to never users, and to have initiated injection behavior earlier in their lives. With respect to current drug use, shooting gallery users were more likely to be daily drug users and to report sexual partners who were also IVDUs. Table 2 compares the characteristics of current shooting gallery users and IVDUs who reported stopping shooting gallery use. Current shooting gallery attenders were, again, male, homosexual/bisexual, younger, less educated, more often homeless in the prior decade, and had a history of injection behavior showing more recent initiation into this culture. No other drug involvement factor differentiated those persisting in shooting gallery use and those who ceased this activity.

Table 3 presents the results of two multiple logistic regression analyses: (1) ever vs never use of shooting galleries and (2) current vs former shooting gallery users. Age was deleted so that year of first IV drug use might be included in the equations. Using multiple regression to characterize those IVDUs who reported ever going to a shooting gallery compared with those with no self-report history of gallery attendance, we found that ever attenders were more likely to be male, homosexual/bisexual, Black, and homeless, to report arrests, drug treatment, and sex partners who were IVDUs, and to have a history of daily drug injection and of starting drug injection earlier, all other variables held constant. Compared to females, males, especially homosexuals or bisexuals, more commonly visited shooting galleries. The comparison of characteristics differentiating individuals who persist in injecting illicit drugs in shooting galleries and those who have stopped showed fewer distinguishing factors once other variables were held constant using multiple regression: recent gallery attenders had somewhat less education, more frequently reported homelessness, and more recently initiated IV drug use. The high OR for male homosexuals or bisexuals who persist in using shooting galleries is of concern because they may serve as a bridge for HIV-1 transmission from gay males who do not inject to heterosexual IVDUs.

Discussion

These data indicate that shooting gallery use is associated with lower socioeconomic status, greater criminal involvement, and indicators of heavier drug use—characteristics congruent with prior ethnographic reports of street drug users.[15–17] Our findings suggest that the use of shooting galleries is in part a pragmatic response to the contemporary context of illicit drug use, namely, that IVDUs seek access to needles for injecting drugs that are illegal to possess.[18] Shooting galleries provide needles in relatively clandestine locations, also reducing the threat of arrest for drug use and drug and drug paraphernalia possession.[19,20] However, the lack of financial resources associated with shooting gallery use fails to differentiate IVDUs who have stopped using shooting galleries from those that persist in this behavior, with the exception of greater reports of homelessness among re-

cent shooting gallery users. Homeless individuals are more likely to frequent shooting galleries and to persist in this behavior, thereby providing some limited evidence supporting an hypothesis of economic necessity. The traditional view that needle sharing reflects a culturally entrenched ritual resistant to change[21] has been expanded to acknowledge a pragmatic response of IVDUs to the restricted availability of needles and syringes.[22] Lessons learned from studies of needle sharing offer some insights into the complexity of this social behavior but appear insufficient to fully explain its continued existence.

While going to shooting galleries may be pragmatic from a sociolegal and economic perspective, using needles obtained from shooting galleries is associated with increased risk of acquiring HIV-1 infection. The extent of exposure to HIV-1 in shooting galleries was unknown until recently. Chitwood et al.[23] obtained 148 needles and syringes from three shooting galleries in Miami, of which 10.1% tested positive for HIV-1 antibody. This relatively high rate of exposure found in shooting galleries may reflect frequent reuse of equipment as well as sharing equipment more frequently with strangers or acquaintances whose HIV-1 antibody status may be unknown (as compared to sharing needles among groups of close friends).[24,25] In our study, the odds of having antibody to HIV-1 among those who have ever gone to a shooting gallery were nearly twice the odds for those who had reported never attending a gallery.[8] Vigorous prosecution of drug paraphernalia offenders may act to facilitate transmission of HIV-1 infection rather than reduce its spread.

One public health approach to the problem of HIV-1 transmission in shooting galleries is to offer sterile needles through needle exchange programs.[26-28] This approach generally has been considered incompatible with current policies on drug use in most US jurisdictions. A recent report[7] discusses public health preventive interventions to reduce the risk of HIV-1 among users of shooting galleries in the context of the current legal climate—educating proprietors of shooting galleries to educate their clients and to improve needle sterilization practices. This approach requires the active participation of shooting gallery operators in creating "safer" galleries; additional studies will be required to determine the extent to which such interventions are feasible and effective. Ultimately, a goal for reducing the transmission of HIV-1 infection among IVDUs would involve the cessation of shooting gallery use, rather than attempts to create "safer" galleries. Study results presented here suggest that although a large proportion (37%) of IVDUs reporting ever going to shooting galleries have recently stopped, the majority persist in this activity. Data on AIDS knowledge and attitudes posed to these participants demonstrated no trends differentiating these three groups of gallery users.

A focus on risk reduction among homosexual or bisexual males who inject drugs in shooting galleries seems to be of paramount importance. Although patterns of shooting gallery use fluctuate over time and our classification into three distinct groups based on recent history may be arbitrary, no distinct trends in use were detected as related to the risk factors assessed. Although other studies report behavior change among IVDUs in response to the HIV-1 epidemic,[29] these

studies note that a substantial proportion of IVDUs persist in risk-increasing behaviors.[30] Further, studies have shown that although some IVDUs who engage in needle sharing practices are knowledgeable about modes of transmission,[31,32] they do not perceive themselves to be at high risk for infection.[33] These data are consistent with previous reports[29,30] indicating that a large proportion of IVDUs continue to engage in high risk behaviors, despite their knowledge about HIV-1.

The characteristics of those who continue to use shooting galleries suggest that we need to target IVDUs earlier in their careers, before this behavior becomes firmly entrenched, and to focus additional interventions on an especially difficult-to-access subset of IVDUs—those who are less educated and impoverished. Paradoxically, those who persist in using shooting galleries are also likely to report a history of drug treatment, a characteristic shown to lead to reduced IV drug use[34] although relapse is frequent.[35] However, those who continue going to shooting galleries are not necessarily more frequent drug users than those who have stopped, suggesting that overall drug involvement is not a discriminating characteristic. HIV-1 prevention efforts must strive for greater access to IVDUs who use shooting galleries in order to appropriately target messages on cessation of shooting gallery use. Prevention efforts should also consider the approach suggested by Chitwood et al.[23] and articulated by Des Jarlais and Friedman[7] of making galleries safer for those who use them. ☐

Comparing the Predictive Accuracy of Health Risk Appraisal: The Centers for Disease Control Versus Carter Center Program

Julie A. Gazmararian, MPH, Betsy Foxman, PhD, Louis Tze-Ching Yen, PhD, Hal Morgenstern, PhD, and Dee W. Edington, PhD

ABSTRACT

Background. From 1986 to 1987 the Carter Center of Emory University joined with the Centers for Disease Control (CDC) to develop a new, probability-based, adult health risk appraisal (HRA) instrument for the public domain. This new instrument is compared with the CDC HRA version to determine which is a more accurate predictor of mortality.

Methods. We compared predicted mortality risks from the CDC HRA and the Carter Center HRA with the observed mortality among 3135 smokers and never-smoking persons, aged 25 to 60, followed from 1959 to 1979 as part of the Tecumseh Community Health Study.

Results. When individuals were classified according to the difference between their actual age and risk age, for the CDC HRA, there was a progressively increasing risk of 10-year mortality as the difference increased. The Carter Center HRA did not show this trend. An analysis using relative operating characteristic curves showed that the mortality risk predictions for both programs were very similar for men and women. However, differences between actual age and risk age for the two programs were not similar for men or women, particularly older men. Therefore, actual age minus risk age for the CDC program was a more accurate predictor of 10-year mortality than was this difference for the Carter Center program.

Conclusions. The results from both types of analyses suggest that the validity of risk ages obtained from the Carter Center version may not be sufficient to justify updating programs for those currently using the CDC instrument. (*Am J Public Health.* 1991;81:1296–1301)

Introduction

The health risk appraisal (HRA) has become a popular approach to help people identify the risks associated with personal characteristics (biological, life-style, family history).[1] Risk factors identified from various epidemiologic studies are combined with mortality statistics in order to assess an individual's risk of mortality within the next 10 years. An individual's risk is usually expressed as risk age (or appraised age), which enables one to compare one's own modifiable risk with that of a cohort. Thus the HRA could be a reasonably efficient method for transmitting this mortality risk information to individuals and stimulating them to change in terms of attitudes, beliefs, and life-styles, if so indicated.[2,3]

Although there are numerous variations of the HRA instrument, the majority are adapted from techniques developed by Robbins and Hall.[4] The accuracy of the mortality predictions from this methodology has been questioned repeatedly.[1–3,5–9] For example, Smith et al.[10] report that this method systematically overestimates the probability of mortality from coronary heart disease when the predictions are correlated with those from the Framingham Heart Study and the Risk Factor Update Project. Foxman and Edington assessed the accuracy of the Centers for Disease Control (CDC) HRA by comparing HRA-predicted risks of mortality with deaths that actually occurred among 3135 persons followed from 1959 to 1979 as part of the Tecumseh Community Health Study.[7] They found that the differences between actual age and CDC HRA risk age correctly classified individuals into high- and low-risk groups.

In an effort to update the scientific base of the HRA instrument, the Carter Center of Emory University joined with the CDC from 1986 to 1987 to develop a new, probability-based, adult health risk appraisal instrument for the public domain. The result of this project is "Healthier People," the Carter Center of Emory University Health Risk Appraisal Program.[11] The Carter Center HRA incorporates mortality tables from 1980 to 1982; integrates recommendations from the Breslow Risk Factor Update Project; uses regression equations from heart attack and stroke estimates developed by the Framingham Study; employs new models for cancer estimates developed from National Cancer Institute data; corrects height-weight recommendations; includes high-density lipoprotein as a risk factor; eliminates race as a predictor variable, so that mortality estimates are based only on age and sex; replaces the credit-debit method with multivariate statistical techniques; adjusts reference mortality projections for causes of death where risks are quantified by nonmodifiable precursors, so that individuals are not penalized if they have high levels of fixed risk, e.g., family history of breast cancer, diabetes, etc.; and calculates an individual's risk from 19, rather than 11, quantifiable causes of

death. The Carter Center promises continuous updating of software as new scientific findings are determined and evaluated and technical enhancements developed.[11,12]

We have compared this new HRA instrument (version 3.1, released in late 1988) with the CDC HRA version that was used in our previous study[7] to see if this new version more accurately predicts mortality. This comparison has important implications for those using the HRA instrument for scientific and research purposes as well as for those using it for health education or intervention.

Methods

As in our previous study,[7] data available from the Tecumseh Community Health Study were used as input to the HRA programs. In order to compare the two instruments, we calculated the average HRA-predicted 10-year mortality risk (predicted risks) and risk age for both programs.

Risk age is defined for a given individual as the expected age of someone in the reference population of the same age, sex, and other fixed characteristics for whom the average 10-year mortality risk is the same as the HRA-predicted 10-year mortality risk. Thus, for the CDC HRA method a risk age of 50 for a 40-year-old White male means that the 10-year mortality risk predicted for that person is equal to the life-table estimate of the 10-year mortality risk for a 50-year-old White male in the 1975 to 1977 US population (the reference population for the CDC HRA). Hence this 40-year-old person is in poorer health than someone of the same age, sex, and race in the reference population.

The Carter Center HRA compares the predicted risk to the cohort average risk mortality, i.e., the population average risk for a person of the same age and sex adjusted for the presence of nonmodifiable risk factors.[11] Thus an individual with a family history of breast cancer would be compared with a reference population different from that of an individual without a family history of breast cancer. This reference mortality adjustment is made only for causes of death where risks are quantified by nonmodifiable precursors (US population projections are used as the reference mortality for all other causes of death).[12] A detailed comparison between the CDC HRA and the Carter Center HRA calculation of an individual's predicted risk of mortality and risk age is outlined in Appendix A.

Data Instruments

The Carter Center HRA (version 3.1) computes health risks based on a 45-item questionnaire[11]; the CDC HRA uses a 37-item questionnaire.[13] Twenty-nine of the 45 questions for the Carter Center HRA and 31 of the 37 questions for the CDC HRA are used directly for computation of risk (predicted risks and risk age, Appendix B). These questions were selected by the program's developers for their presumed causal relationship rather than mere statistical association. When items are not answered, both programs assign population norms.

Study Population

The Tecumseh Community Health Study began in 1959 as a comprehensive prospective investigation of health and disease in a community.[14] The principal aim was to identify causes and precursors of coronary heart disease, hypertension, chronic respiratory disease, diabetes mellitus, and other chronic diseases. Mortality ascertainments were completed successfully on more than 99% of previously examined subjects on three occasions, the most recent being 1978 to 1979.

In the 20-year period following the first cycle of examinations, 1059 (12.3%) of the 8641 participants died. Since the HRA is considered most accurate in the 25- to 60-year age range, we limited our analyses to the 3762 persons aged 25 to 60 in 1959 to 1960. Time since stopped smoking was not available for the 564 former smokers but is required by the CDC HRA; excluding former smokers from the current study restricted our sample to 3198; vital status after 10 years was available for 3166, and 3135 had sufficient information to calculate HRA. Thus a total of 3135 never-smoking or currently smoking individuals aged 25 to 60 in 1959 were included in this analysis.

Of the 29 variables used by the Carter Center HRA in predicting risk age, 13 were collected during the 1959 to 1960 Tecumseh survey, and 14 of the 31 variables used by the CDC HRA were available (Appendix B). Some recoding of the Tecumseh survey responses (mainly collapsing of categories to correspond to the precoded responses of both HRAs) was necessary for six of the variables. Although the wording was somewhat different in the two HRA instruments, the meanings were judged to be the same.

Data Analysis

Using both programs for each individual from data gathered during the 1959 to 1960 Tecumseh Community Survey, we compared the predictions of the CDC HRA with the Carter Center HRA, calculating the average HRA-predicted 10-year mortality risk from all causes (predicted risks) and risk age. The difference between each individual's age at the baseline survey and risk age (age difference) was compared by gender and age groups. To determine if risk age was a good predictor of observed mortality, we examined the proportion dying at 10 years for both men and women by the difference between actual age and risk age. The average HRA-predicted mortality risk, observed mortality, and age-adjusted mortality risk were calculated for each category of this difference between actual age and risk age. Since variations in age, sex, and race explain much of the variability in death rates, examining the gender, age, and race-specific differences between actual age and risk age represents the contribution of nondemographic inputs to the HRA.[15]

In order to assess which instrument more accurately predicted mortality, we performed relative operating characteristic (ROC) curve analysis[16] to compare both the predicted risks and the difference between actual age and risk age for each prediction method. ROC curve analysis plots the proportion of individuals correctly classified among those who died (true-positives/deaths = sensitivity) versus the proportion of individuals incorrectly classified among those living (false-positives/survivors = 1 − specificity) for various cut points of the predictor score, i.e., predicted mortality risk or age difference. A center line is called the "chance line" because, for every point, the probability of a true-positive response equals the probability of a false-positive response, i.e., does not predict any better than chance. The greater the area of the curve above this chance line, the greater the predictive accuracy of the instrument (HRA program). Points below the diagonal reflect values of false-positive greater than those of true-positive, i.e, worse results than would be expected by chance alone. Statistical tests were conducted using the Corroc2 program[17] in order to compare the ROC curves of the CDC and Carter Center HRA programs.

[b] Age-adjusted risks for each sex and HRA method are predicted from the results of four logistic regression models, where each category of risk is transformed into dummy variables and the average risk (−1 to +1) category is left out of the model; age is set equal to 39.6 years (the total sample mean).

[c] Expected to be lowest risk category.

Results

All 3135 never- or current-smoking, 25 to 60 year olds in the 1959 to 1960 Tecumseh Community Health Survey included in this study were White, and 48% were male. Observed mortality risk was 5.3% after 10 years and 13.9% after 20 years.

Correlation of HRA Predictions and Comparison of Difference between Actual Age and Risk Age

Predicted risks of mortality from the two programs were highly correlated (Pearson's r = .81; 95% confidence interval (CI) = 0.78, 0.84), as were the risk ages (Pearson's r = .92; 95% CI = 0.88, 0.95). These correlations remained high when examined by age group and sex. However, the difference between risk age and actual age (age difference) for the two methods was not correlated (Pearson's r = .18; 95% CI = 0.14, 0.21). The average age differences were −0.8 years for the Carter Center HRA and −4.2 years for the CDC HRA. The average age differences between the two programs were 3.4 years (95% CI = 3.2, 3.6) overall, 5.9 years (95% CI = 5.6, 6.2) for men, and 1.1 years (95% CI = 0.79, 1.4) for women. This difference increased when stratified by actual age.

Comparison of 10-Year Mortality Risks by Difference between Actual Age and Risk Age

A risk age that is the same (−1 to +1 category) as actual age signifies that the individual is at an average risk level for his/her age, race, and sex for the CDC HRA (and for Carter Center HRA presence of nonmodifiable risk factors). Thus, we would expect to see an increase in observed mortality risk as the difference between actual age and risk age increases (from > +1 category to < −10 category). The predicted, observed, and age-adjusted mortality risks by age difference are shown in Tables 1 and 2. Overall, the CDC HRA program classifies more people in the higher risk categories than the Carter Center HRA, and thus the predicted mortality risks are almost double those observed among men (12.65% predicted vs 7.8% observed) and among women (5.35% predicted vs 2.9% observed). In contrast, the Carter Center slightly underestimates these risks among men (6.02% predicted vs 7.8% observed) but overestimates risks among women (4.45% predicted vs 2.9% observed).

With the CDC HRA program, as the difference between actual age and CDC HRA risk age increases for both men and women, so do the predicted risks and the total observed and age-adjusted 10-year mortality risks. Using the Carter Center HRA, the lowest age difference (> +1 category) had a higher predicted and observed mortality risk than the next highest category (−1 to +1), after which risks rise steadily for both men and women (Tables 1 and 2).

Relative Operating Characteristic Curve Analysis

We examined ROC curves for both the CDC and Carter Center HRA-predicted risks by 10-year mortality rates, since HRA predictions are based on the

10-year appraised chance of dying. The ROC curves for both programs were quite similar and were not significantly different from each other for men (P = .925) or women (P = .9775). The HRA predictions by age group for each sex were also examined and showed similar results; predictions were best for those under age 45.

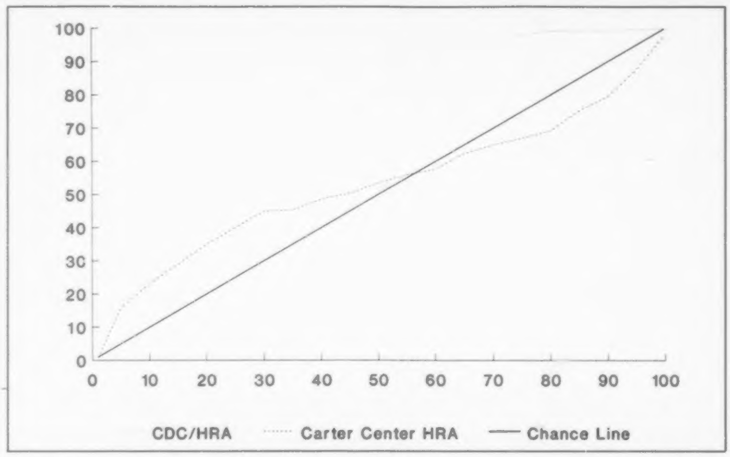

FIGURE 1—ROC Curve Analysis of the Difference between Actual Age and HRA-Predicted Risk Age: Comparison of CDC and Carter Center Methods for *Men*, Using Observed 10-Year Mortality as the Outcome Variable, Tecumseh Community Health Study (n = 1507). Risks were ordered from high to low: CDC difference ranged from −21.5 to 3.7. Carter difference ranged from −16.3 to 7.

The difference between actual age and risk age examined by ROC curves showed that for both men and women (Figures 1 and 2) and within each age group (not shown), actual age minus risk age is a better predictor of mortality with the CDC HRA than the Carter Center HRA. In fact, the ROC curve for the Carter Center HRA was below the chance line for men (Figure 1) but not for women (Figure 2). Thus, for men the Carter Center age difference, on average, predicted 10-year mortality no better than chance alone. As depicted in Figures 1 and 2, these ROC curves were different between the two programs for men (P = .0083) and for women (P = .0257). Further examination of the data in Figure 1 showed that at the point where the Carter Center HRA crosses the chance line (approximately 60%), the difference between actual age and risk age is −3.6 years, whereas for the CDC HRA it is 1.4 years. Moreover, the mean age for those individuals below the chance line (Carter Center) is 43.3 years, and for the same area of the CDC calculations it is 32.7 years. Those individuals below the chance line for the Carter Center HRA were also more likely to be smokers (99.4%) compared with those before the curve crosses the chance line (79.7%).

We also examined this difference by age groups for the two programs. The results were similar for all ages except for those ages 45 to 60, for whom the Carter Center HRA age difference was consistently below the chance line, indicating that it predicted worse than chance alone for this age group (P = .0005).

Discussion

Although mortality risk predictions from the two HRA programs were highly correlated, the calculated risk ages were quite different. It seems unlikely that this result is due to the different reference populations used (the Carter Center program used 1980 to 1982 vital statistics as the reference population and the CDC HRA used 1975 to 1977 vital statistics), because mortality rates have changed little during that time period. More likely, there are differences in how risk age is determined, e.g., mortality risks predicted by the Carter Center more closely approximated those observed than the CDC HRA mortality risks. Further analysis of the specific calculations of risk age is recommended, particularly the implications of using population risk (CDC HRA) versus "adjusted" population risk (Carter Center HRA).

On average, the Carter Center HRA age difference was less than that of the CDC HRA age difference. However, when the age differences for the two programs were compared with the observed 10-year mortality using ROC curve analysis, the CDC HRA age difference was consistently a more accurate (i.e., more sensitive and specific) predictor of individual mortality than was the Carter Center HRA age difference, especially in older men. In addition to performing poorly with the calculation of risk age for older

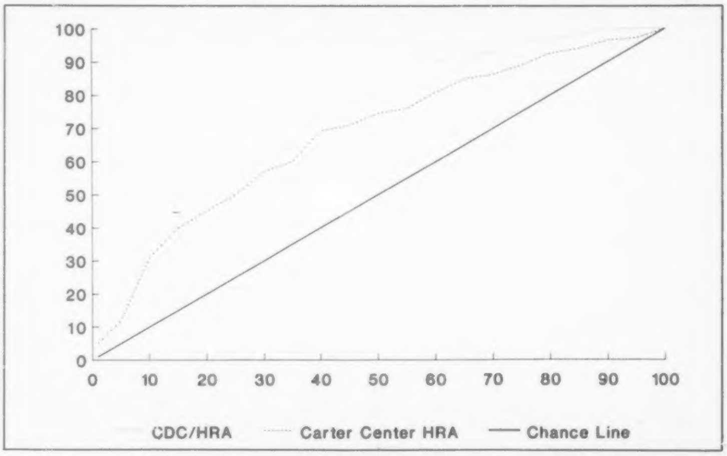

FIGURE 2—ROC Curve Analysis of the Difference between Actual Age and HRA-Predicted Risk Age: Comparison of CDC and Carter Center Methods for *Women*, Using Observed 10-Year Mortality as the Outcome Variable, Tecumseh Community Health Study (n = 1628). Risks were ranked from high to low: CDC difference ranged from −21 to 2.8. Carter difference ranged from −33 to 4.2.

men, the Carter Center HRA may have erred in the weight used for the smoking risk factor.

One of the criticisms of HRA concerns the reliability of self-reported clinical information.[9,10] Reliability was not a problem for blood pressure, weight, and cholesterol in this study, because we used the results of clinical examinations. Although we had data for only approximately 45% of the items used to calculate the predictions (14 of 31 items for CDC/HRA and 13 of 29 items for Carter Center HRA), we did have information on the major risk factors for the common causes of death (e.g., stroke [7.5%], heart disease [39.4%], and lung cancer [5.8%], which accounted for 52.7% of the Tecumseh deaths). Since cardiovascular disease (CVD) is the leading cause of death[18], we also performed ROC curve analysis on the difference between actual CVD risk and predicted CVD risk for each program. The ROC curves for this analysis were virtually identical to those for total mortality; thus the CDC HRA was also a better predictor of CVD mortality.

The variables that we did not have available (e.g., miles traveled per year, social ties) are used as risk factors for less common causes of death, such as motor vehicle accidents and suicide.[8,15] Moreover, we restricted our sample to those individuals older than 25 years of age, and these less common causes of death occur more frequently among younger age groups.[18] Both programs defaulted to population norms for missing values; thus, we would expect the missing items to be extreme to make large changes in the resulting predictions.

Intrinsic errors of the HRA instrument, such as the scientific uncertainty of some risk factors or errors inherent in statistical calculations, will introduce possible problems of accuracy.[15] Our comparison may have been biased toward one program or another because of inherent characteristics of the data used. We attempted to make the comparison as fair as possible by using the same set of variables, calculating ROC curves for 10-year mortality, and using default missing values for each program. Given the constraints of the current software programs and the limitations of the Tecumseh Community Health Study, the CDC HRA appears to be a superior predictor of mortality in the population.

HRA has also been criticized because its effectiveness as a health education/promotion tool has not been demonstrated.[3,8] The revised Carter Center HRA program was primarily developed to update the scientific base of the HRA instrument in order to improve the accuracy of the mortality predictions.[11] If the predictions are improved with this revision, it would seem that this instrument would also be a better health education tool, at least providing more accurate information to the participant. It appears that the revisions did not necessarily improve the mortality predictions (as they were very similar to the CDC HRA mortality predictions) and may have erred on the risk-age calculations for men. If the risk-age calculations are incorrect for a particular program, the effectiveness of that HRA as a health education tool should be questioned. Current HRA users may want to continue using their existing program until the potential problems with the Carter Center Healthier People HRA program are examined further and the effectiveness of the two HRAs in altering behavior has been compared. Those considering the use of the HRA must judge which program better suits the needs of their health education programs. □

APPENDIX A—CDC vs Carter Center Health Risk Appraisal Program Calculation of an Individual's Overall Predicted Risk of Mortality and Risk Age

CDC HRA	Carter Center HRA
Uses age-sex-race-specific mortality rates for 52 causes of death and "all other" causes	Uses age-sex-specific mortality rates for 41 causes of death and "other causes"
The 10-year expected risk of mortality for each leading cause of death is then "adjusted" by the measured risk factors using the credit-debit method	The individual's current cause-specific mortality risk is estimated using multivariate statistical techniques or population average risk
The cause-specific risks of mortality are summed to determine an overall 10-year expected risk of mortality (predicted risk)	The appraised risks for each cause are summed to get the participant's total appraised risk (predicted risk)
This overall total is compared with age-sex-race-specific risks for the general population to determine "risk age," the age for the given sex-race category with the same overall mortality risk as that predicted from the risk factors	The total appraised risk is compared with either the US population projections for causes of death with modifiable risk factors or an adjusted US population projection for causes of death quantified by nonmodifiable risk factors. This comparison determines the individual's risk age

Impact of a Geriatric Assessment Unit on Subsequent Health Care Charges

William B. Applegate, MD, MPH, Marshall J. Graney, PhD, Stephen T. Miller, MD, and Janet T. Elam, BS

ABSTRACT

Background. In a recent randomized controlled trial assessing the efficacy of an inpatient geriatric assessment unit (GAU), we demonstrated that patients assigned to the unit were less likely than those in the usual care group to be admitted to a nursing home and more likely to remain living in the community. Despite evidence of benefits of GAU care, questions remain about its cost. We examine the impact of GAU treatment on subsequent health care charges.

Methods. Sequential referrals of elderly disabled patients considered at risk for institutionalization or likely to improve with rehabilitation were randomized to the GAU or to usual care. Charge data were collected on utilization of a wide variety of health care services starting at the point of randomization.

Results. The group randomized to the GAU experienced significantly higher rehabilitation charges per participant ($1[illegible] 583 vs $2066, $P = .0001$), but lower mean nursing home charges ($1798 vs $3426, $P = .004$). Total health care charges per participant over the 1 year follow-up were greater for the GAU group ($28 406 vs $16 444, $P = .004$). When charges were adjusted per year of life survived, the GAU group still showed a substantial (but nonsignificant, $P = .10$) increase in total charges. However, when charges were adjusted per day subsequently spent residing in the community, adjusted total charges were similar between the two groups.

Conclusion. Our results indicated that improved outcomes from GAU care require an investment in rehabilitation that is not totally offset by decreased institutional charges in the following year. (*Am J Public Health.* 1991;81:1302–1306)

Introduction

The utility of geriatric assessment has recently been examined by several studies and one National Institute on Aging consensus conference.[1-13] Positive effects of geriatric assessment and subsequent treatment have been demonstrated by Rubenstein and colleagues in a Department of Veterans Affairs Hospital setting and by our group in a community rehabilitation hospital.[14,15] Both of these randomized controlled trials of inpatient geriatric assessment units (GAUs) targeted functionally impaired older patients recovering from acute hospitalization. Both studies demonstrated that GAUs improved patient function, decreased long-term institutionalization, and possibly reduced mortality.[14,15] In our trial, GAU patients were more likely to reside in the community at each follow-up interval.

In our trial, randomization to the GAU or a control group was stratified according to whether the patient was judged prior to randomization to be at higher or lower risk of immediate nursing home placement. When data were analyzed by prerandomization strata, subsequent nursing home days were reduced by GAU treatment for both strata, but physical function was improved and mortality was reduced only in the lower risk stratum.

Despite evidence of benefits of GAU care, questions remain about its cost. In the trial conducted by Rubenstein and colleagues,[14] treatment on the GAU resulted in decreased estimated health care costs per year of life survived. During our study we collected data on both reimbursed and unreimbursed health care utilization charges after randomization and validated the data in an extended data collection project. This article describes the impact of GAU treatment on these charges, both for the entire study cohort and for the two risk strata.

Methods

Patients

Patients who were considered by physicians and social work personnel to be functionally impaired and at risk of nursing home placement were referred to the GAU. Inclusion and exclusion criteria and the screening process have been described previously.[15]

During the 2-year enrollment period 278 referrals were received. Of these, 123 (44%) were determined to be ineligible for the following reasons (percents are of total consultations): medically unstable, 18 (6.5%); terminally ill, 12 (4.3%); too severely cognitively impaired, 34 (12.2%); not sufficiently medically or functionally impaired, 12 (4.3%); refused consent, 21 (7.6%); nursing home placement inevitable, 8 (2.9%); and miscellaneous, 18 (6.5%). The remaining 155 patients were randomized, 77 to the control group and 78 to the GAU group.

Randomization. Randomization was conducted in a stratified block design. Patients were stratified prior to randomization according to an assessment of their risk of immediate nursing home placement at hospital discharge. This assessment

was based on patient and physician estimate of likelihood of nursing home placement and identified two strata with different levels of risk for subsequent nursing home placement.[15] The methodology for stratification and randomization has been published previously.[15]

The Geriatric Assessment Unit. The GAU studied was a 10-bed geriatric unit based in a rehabilitation hospital that is a separate building in the Baptist Memorial Hospital complex. The organization, specific staff roles, and function of this multidisciplinary unit have been described previously.[2,16] The GAU provided equal emphasis on interdisciplinary assessment of patient problems and on rehabilitation. Particular attention was paid to problems common in frail hospitalized older patients, including incontinence, decubitus ulcers, contractures, confusion, sensory disorders, depression, medication toxicity, inadequate nutrient intake, weakness or lack of motivation, inability to perform activities of daily living (ADL), gait disorders, falls, and degree of family and social support.

After completion of the initial GAU assessments, the first of a series of weekly team meetings was held to determine whether or not the patient was a candidate for a specific treatment and/or rehabilitation. Patients needing medical care were either treated on the GAU or returned to the care of the original referring physician. A rehabilitation plan with specific goals was developed for patients needing rehabilitative care, and patient progress was reevaluated weekly. After discharge from the GAU, patients were returned to their regular physicians and received no further specialized intervention.

Control Group. GAU or research staff made no arrangements for postrandomization care of control group patients. Instead, control group patients received services that they or their physician chose from among options available to any patient, but excluding treatment on the GAU.

Measures

Patient evaluations were made prior to randomization and at 6 weeks, 6 months, and 1 year after randomization. Postdischarge interviews were conducted in the patient's place of residence. All data were collected by trained interviewers who did not provide clinical care but who could not realistically be blinded to group assignment. Data collected included demographic variables, place of residence, self-reported physical activities ranging from basic ADLs to ability to move heavy objects,[17] observed timed physical performance,[18] the CES-D Depression Scale,[19] the Folstein Mini-Mental State Exam,[20] and data on charges.

Charge data were collected on subsequent hospital utilization, physician services, nursing home utilization, inpatient and outpatient rehabilitation, home health care, homemaker/sitter care, medication charges, equipment charges, and other miscellaneous health care-related charges. At the time of randomization, each patient was given a charge data notebook that contained a brief description of the study, a list of possible charges that might be incurred, a chart to record charges, and pockets to store bills, receipts, etc. At the 6-month interview these notebooks were reviewed and, if necessary, patients were reinstructed in charge documentation. At the 1-year interview the notebooks were collected, reviewed with the patient or a family member, and any additional undocumented charges and their sources were noted.

We also constructed a simplified form in layman's language that listed possible categories of health care charges (e.g., hospitalizations, nursing homes, home health care, equipment), asked for the source of these charges (e.g., name of institution, pharmacy, health care agency), and included some open-ended questions such as "Have you been in a nursing home or had someone to care for you in your home?" In cases where a family member or other financial advisor was the responsible party, we mailed the simplified form along with a letter of explanation and a copy of the signed consent form. Follow-up telephone calls were often necessary to verify and explicate charges listed on forms. Telephone calls were also made when forms were not returned, and data were collected from a family member if necessary.

Charge data for all hospital stays, rehabilitation stays, skilled care nursing stays, and home health care were verified with the sources of care. All cooperated, including public and private institutions throughout the United States. Also, length of stay and daily rate were verified with source of care for nursing homes and board and care homes.

For physician, dentist, optometrist, pharmacy, and equipment charges, bills or receipts were used if available. If not, charges were obtained from the source of care. In the few cases where ledger cards of deceased patients had been destroyed, estimates of physician charges were made from the patient's medical record. Medicine charges for which documentation was unavailable were estimated by the patient or family and this estimate was cross-checked with the 1986 *Pharmacy Redbook.*[21] Physician charge data were cross-checked with pharmacy documents to identify otherwise unreported charges.

Because private home care is overlooked in many studies of health care charges, a special attempt was made to collect charge data for private duty nurses, sitters, housekeepers, and paid companions who were hired because of the patient's medical condition. Patients with substantial home care charges generally had a responsible family member who could provide charge data. Also, a large home care registry cooperated fully in providing charge information.

Valid charge data were collected on 152 of 155 randomized patients. Control group data were lacking for one patient who withdrew at 6 weeks and would not allow further data collection and two patients who could not cooperate due to mental status deficits and whose families refused to cooperate.

Statistical Analysis

Equivalence of study groups was tested using Student's t test of differences between means of two independent samples (pooled estimate of population variance) for continuous variables or the chi-square test of statistical independence for categorical variables.[22] All analyses used the intention to treat approach. All statistical tests were nondirectional, with $P < .05$ used as the criterion of statistical significance. Unless specified otherwise, data reported here on utilization and charges represent group means.

Results

The baseline demographic characteristics and functional status of the 152 patients included in this report were similar to those in the study cohort of 155 reported previously.[15] Characteristics of this study cohort included mean age of 78 years, 78% female, 25% married, and 52% living alone. The cohort exhibited substantial functional impairment with 86% rated either moderately disabled (dependent on 3–6 out of 8 ADLs) or severely impaired (dependent on 7 or all ADLs).

There were no significant differences at the time of randomization between the GAU group and the control group in base-

TABLE 1—Absolute Dollar Charges and Charges per Year Survived[a]

	Absolute Dollar Charges			Charges per Year Survived		
Source of Charges	GAU[b]	Control	P[c]	GAU[b]	Control	P[c]
Rehabilitation units[d]	10 583 ± 6302	2066 ± 4654	.0001	18 406 ± 26 256	2215 ± 4795	.0001

line demographic data, scores on the CES-D Depression Inventory, the Mini-Mental State Exam, ADLs, measures of timed physical performance, or types of diagnoses.

Analysis of baseline characteristics of the strata at higher vs lower risk for immediate nursing home placement revealed that the higher risk strata had significantly longer length of initial hospital stay and higher levels of dependence in ADLs at baseline. Age, race, sex, marital status, and prior residence did not differ between the two strata.

Table 1 compares the charges for the GAU vs control groups during the 12 months of follow-up after randomization. The GAU group had significantly higher charges for inpatient rehabilitation (P = .0001) and absolute total charges over the year of follow-up (P = .004). Because admission to the GAU allowed rapid placement, the GAU group had significantly lower hospital charges immediately after randomization (P = .004). The GAU group also incurred significantly lower nursing home charges (P = .05). However, in computing total absolute charges, these lower nursing home and initial hospital charges were not of sufficient magnitude to offset the GAU group's higher rehabilitation charges. As can be seen in Table 1, there were no statistically significant differences between the groups for any other category of absolute charges.

Analysis of the charge data by risk strata (not shown in Table 1) indicated that absolute total charges for the GAU group in the higher risk stratum were significantly higher than those for the corresponding control group for 1 year after randomization ($38 793 vs $16 514 per participant, P = .02). As expected, rehabilitation charges were significantly higher for the high-risk GAU group than for the high-risk control group ($13 118 vs $1888, P = .0001). In the higher risk stratum, mean subsequent nursing home charges tended to be lower for the GAU group ($3078 vs $4826, P = .28) over the year of follow-up, but these differences were not significant and did not offset the overall higher rehabilitation charges. In the lower risk stratum, the GAU group had significantly higher rehabilitation charges compared to the control group ($9164 vs $2168, P = .0001) and the GAU group showed a trend toward higher total charges during the 12-month follow-up period ($22 590 vs $16 404, P = .06). Again, the GAU group in this stratum showed a trend toward lower subsequent nursing home charges ($1081 vs $2621, P = .10), but this trend was not enough to offset overall absolute charges.

Charges were also adjusted per year of life survived to account for persons who died (Table 1). Even when adjusted per year of life survived, the GAU group had significantly higher mean charges than the control group for inpatient rehabilitation ($18 406 vs $2215, respectively; P = .0001). The GAU group had significantly lower adjusted hospital charges immediately after randomization ($279 vs $3148, P = .005) and nursing home charges ($2292 vs $4866, P = .03). The GAU group also demonstrated a trend toward lower medication charges ($539 vs $731, P = .06). However, total adjusted (per year of life survived) charges across all categories were still higher for the GAU group ($60 292 vs $28 134, P = .09), but this difference did not reach statistical significance. However when total charges were adjusted per subsequent day of life spent in the community, the total charges were similar for the two groups ($246 vs $331 per participant).

Discussion

We previously reported that a randomized clinical trial of a geriatric rehabilitation unit in a community rehabilitation hospital had favorable results in allowing elderly persons to continue their residence in a home and demonstrating improved physical function.[15] This article extends those observations by addressing the question: "What are the financial investments required to achieve these outcomes?" Our results indicate that if broadly defined medical care charges are used as the measure of subsequent economic expenditures, improved outcomes require an investment in rehabilitation that is not recovered during the following year. When total unadjusted charges during the 12 months of follow-up were analyzed, a statistically significant increase in absolute total charges for health services was observed for the GAU group. This increase in charges was produced primarily by rehabilitation charges. The mean charge for subsequent nursing home services in the GAU group was less than the comparison group, reflecting the greater likelihood that a patient rehabilitated in the GAU would remain living in the community. However, the difference in mean charges for nursing home services between GAU and comparison groups did not fully offset the greater charges for care in the rehabilitation hospital.

Absolute charges provide one economic perspective, but they can be misleading because patients who die do not generate further health care charges. Also, absolute charges may indicate perspectives of payors but ignore the residential and functional status of the patient. To counteract these problems, findings were also analyzed as charges adjusted per year of life survived and per day of life spent in a community setting subsequent to randomization. Total charges per year of life survived were still substantially higher for the GAU group, but did not reach statistical significance after adjustment. When the total charges for the GAU and control groups were adjusted per day of life spent in a community setting, there was neither a significant difference between the two groups in total charges nor a substantial trend indicating some potential difference. Therefore, although absolute total charges for the GAU group were significantly greater in the year subsequent to randomization, this expense was balanced by the fact that GAU patients had fewer nursing home admissions and were more likely to remain in a community setting.

This study obtained data on actual charges rather than estimating costs. Both approaches have strengths and weaknesses. Health care charges do not necessarily reflect actual costs for delivering a service. On the other hand, estimating costs involves judgments that can have substantial impact on the direction of the ultimate results.[23] Few institutions currently have accurate cost data available. We chose to use actual charges rather than estimated costs because charges more clearly reflect the actual expense of GAU and subsequent care to patients or payors, given current reimbursement methods. A potential limitation of our charge data concerns the reliability of the charge data for noninstitutional services. Items such as housekeeper, home health services, and pharmacy charges may be remembered less reliably. However, we did make every effort to document these categories of charges with source of care and the relatively small magnitude of noninstitutional charges is such that some inaccuracy in these data would not alter the findings of the study.

In the trial conducted in a Department of Veterans Affairs Hospital using estimated costs, GAU patients had similar absolute costs when compared to control patients ($19 406 for the GAU vs $20 329 for the control).[14] When these costs were adjusted per year of life survived, the GAU had lower costs than the control group ($22 597 vs $27 826, respectively). By comparison, in our study, GAU care actually resulted in higher total absolute charges over the 1-year study period. Further, when charges were adjusted per year of life survived, the GAU group still demonstrated a trend toward higher total charges over the year of study, although this difference was not statistically significant. These findings are different from those reported by Rubenstein et al.[14] because our GAU had much higher absolute daily charges. However, higher charges in the community hospital GAU in this study may reflect reimbursement strategies rather than the actual costs essential to mount a successful GAU intervention. Also, our GAU group tended to have higher subsequent hospitalization charges, while the opposite was true in the Rubenstein study. However, all of our study participants were returned to their usual source of care after the GAU while participants in the Rubenstein study continued to receive specialized follow-up care. This difference in design might account for our different findings with regard to subsequent hospital utilization.

The cost-effectiveness data presented here demonstrate an important issue for health policy analysis of services provided to frail older persons. Although absolute charges may be higher for a new form of health care delivery, analysis of charge or cost data should include some form of adjustment per unit of benefit received. Our study found that GAU care led to greater total absolute charges and greater charges per year of life survived. However, when charges were adjusted per day subsequently spent residing in the community, total charges between the two groups were similar. ☐

Important Aspects of Right-to-Know Legislation Not Being Used by Communities, Say Tufts Researchers

Although communities can obtain specific information about the manufacture, use, storage, transportation and emission of toxic chemicals within their borders, local planning committees generally have not been using such information to prevent pollution or reduce risks, according to a study done by researchers at Tufts University's Center for Environmental Management.

"An in-depth study of four communities suggests that the right-to-know aspects of the 1986 federal Emergency Planning and Community Right-to-Know Act may be taking a back seat to emergency planning activities," said Kathleen Rest, former project manager and assistant professor of occupational and environmental health at the University of Massachusetts Medical Center. "Such information could be used to persuade local governments and industry to go beyond emergency planning and get involved in accident prevention, risk reduction, and pollution prevention activities," she said.

Congress passed the act, also known as SARA Title III, in 1986, partly in response to the chemical disaster in Bhopal, India, which killed more than 2000 people and injured another 100 000. The law requires communities to establish local emergency planning committees (LEPCs) to develop emergency response plans for such environmental disasters using information previously unavilable to local officials, emergency responders, and citizens.

"So far, LEPCs may be taking a narrow view of their authority and responsibility. These committees could play an important role in prevention, but they will have to be persuaded, and they will need help," Rest said.

The study focused on four communities with different types and levels of industrial activity: Springfield, Mass.; Baytown, Texas; Texas City, Texas; and Newark, New Jersey. The researchers looked at how all local communities involved in the Title III activities obtained, used, interpreted and communicated information about hazardous substances in their communities.

"It's a lost opportunity," said Sheldon Krimsky, principal investigator and professor of urban and environmental policy at Tufts. "The LEPCs could play a more proactive role, but they are going to have to help local citizens understand what the new information means," he said.

The researchers identified specific problems and made recommendations on how to improve the implementation of the law's community right-to-know provisions:

- The US Environmental Protection Agency could organize a task force to discuss realistic roles for the LEPCs and provide guidelines for their involvement in prevention activities.
- LEPCs could be encouraged to be inclusive of all community interests when it appoints community members.
- The LEPCs could share data on accidental releases, chemical inventories, and emissions with public health officials.
- The media could play a significant role in making risk information accessible to the public.
- Grassroots citizen and environmental groups have been successful in motivating citizens to take action about toxic hazards issues. LEPCs should work with these groups to enhance public involvement.
- LEPCs should become forums for constructive interaction between citizens, local government, industry, and the public health community.

"If Congress would provide funding to support state and local community activity, and if states would enact statutes to fund Title III activities through fees or appropriations, then the committees would have some incentive to extend their purview and become more effective advocates for prevention activities," said Krimsky.

Mortality of Intravenous Drug Users in Rome: A Cohort Study

Carlo A. Perucci, MD, Marina Davoli, MD, Elisabetta Rapiti, MD, Damiano D. Abeni, MD, and Francesco Forastiere, MD

ABSTRACT

A historical cohort study was carried out in Rome to examine overall and cause-specific mortality among intravenous drug users (IVDUs). A total of 4200 IVDUs (3411 men and 789 women) enrolled in methadone treatment centers between 1980 and 1988 were studied. There were 239 deaths during the follow-up period. The overall SMR was 10.10 in the entire cohort (95% confidence interval, 8.86–11.47), 9.30 in males and 18.07 in females. A large excess of mortality in both sexes was found for infectious, circulatory, respiratory, and digestive diseases as well as for violence, overdose, AIDS, and unknown or ill-defined causes. Tumors and suicide were excessive only in males. Deaths due to drug overdose, violence or trauma, and cirrhosis accounted for 63.6%, AIDS for 7.1%, endocarditis and other bacterial infections for 7.1%, and neoplasms for 3.8% of total mortality. These findings document serious health consequences of drug abuse in Italy. (*Am J Public Health.* 1991;81: 1307–1310)

Introduction

Since the emergence of the acquired immunodeficiency syndrome (AIDS) epidemic most studies have focused on HIV incidence, prevalence, and risk behaviors among intravenous drug users (IVDUs)[1–5] with less attention devoted to overall morbidity and mortality data in this population. There are some indications, however, that IVDUs are at increased risk of overall mortality, deaths from overdose, trauma, infectious diseases.[6–12] This study describes the pattern of mortality in a large cohort of IVDUs in Rome during the period of transition into the "AIDS era."

Methods

Twenty Public Treatment Centers (PTCs) for drug abuse are operating in Rome (population=3 million) since the 1980s. PTCs are open to drug users who reside in each catchment area and agree to a specific outpatient treatment plan. Short-term detoxification with low-dose methadone is currently offered, but subjects usually undertake several methadone cycles.[13]

The three largest PTCs were selected for the study. Information from their clinical records allowed us to enroll a cohort of all the drug users who presented at least once to one of these three centers during the period 1980–1988.

Vital status as of December 31, 1988 was ascertained through the registry office of the last municipality of residence. Cause of death was ascertained through record linkage with the national mortality file for deaths occurring between 1980 and 1987.[14] For deaths occurring in 1988 or not found at the linkage procedure, death certificates were retrieved from the municipality of death and coded by an experienced nosologist according to the ninth revision of the International Classification of Diseases (ICD-9).

For the calculation of person-years at risk of dying,[15] each subject was considered from the date of first enrollment through the end of 1988 or to the date of death. Standardized mortality ratios (SMRs) and their 95% confidence intervals (CI)[16] were used to compare the mortality experience of drug users with that of the total national population. The expected number of deaths was calculated using sex- and age-specific national mortality rates.

Results

A total of 4473 subjects were initially enrolled; 273 were excluded because the identifying data on their records were insufficient to verify vital status, yielding a final sample of 4200 IVDUs (Table 1).

There were only 23.7 expected deaths compared with the 239 observed (SMR-10.10, 95% CI=8.86–11.47) Tables 2 and 3 show sex- and cause-specific mortality. Excess mortality was found for both sexes in all categories. The excess mortality is mainly due to overdose at 3.38 deaths/1000 person-years for both sexes, but violence (1.62/1000 person years) and

[a] Public Treatment Center.

[b] Subjects lost to follow-up were considered alive as of December 31, 1988.

cirrhosis (0.88/1000 person years) also contribute. One AIDS death was recorded for the first time in 1986 (0.4/1000 person years); the AIDS death rate increased rapidly in 1987 (7 deaths, 1.6/1000 person years) and 1988 (9 deaths, 2.7/1000 person years).

The SMR for all causes is higher among females than among males even though the excess rates are similar (9.1 and 8.5/1000 person years in males and females, respectively). An increased mortality from suicide is seen only among males; on the other hand SMRs for pneumonia and septicemia are higher in females. Finally, the SMR for malignancies is higher only in males.

Discussion

The study shows that risk of death increased tenfold in male and twentyfold in female IVDUs. The excess risk of death is observed for most causes of death, including neoplasms in males.

Our study population may be different both in character and in exposure to toxic substances from street addicts and occasional users, thus limiting the generalizability of the results. Moreover, IVDUs are a dynamic population, with some current users permanently stopping drug use each year, but we could not take these changes into account because no information was available.

National standards rates were employed to increase the stability of reference numbers, especially in the young population. However, a more restricted reference population, i.e., Rome, would have assured comparability. Therefore, we examined the cause-specific SMRs for 15- to 34-year-olds in the city of Rome compared to Italy during the period 1980 to 1984; SMR values approximate unity for all categories except overdose, endocarditis, and violence with SMRs of 3.7, 1.67, and 0.73, respectively. On that basis, only slightly different results could have occurred using local standards.

We could not control for other potential confounders (i.e., social class, smoking, and alcohol consumption) besides age and sex. Part of the increased risk of death could be explained by the fact that the educational level and the occupational status of our cohort members indicate a lower social class level. However, a study performed in Northern Italy showed that the differences in the overall mortality for social class are not greater than twofold.[17]

Our data agree with published findings about an excess mortality for cirrhosis, endocarditis, septicemia, trauma, suicide, noninfectious heart disease, and AIDS.[6–12, 18,19] Unlike a study performed in New York City, we did not find an excess mortality from tuberculosis[19]; on the other hand, an Italian report showed only a marginally increased risk for tuberculosis among seropositive drug injectors.[20] Females seem more prone to death due to infectious agents (pneumonia and sepsis). We have no explanation for such differences or data to support Stoneburner and colleagues' hypothesis that some of these deaths could be due to undiagnosed HIV-related diseases.[12,19]

Deaths from overdose due to opiates are high. Most of them (72 of 81) occurred when subjects had been out of treatment for more than 2 weeks. It should be noted also that overdose deaths are probably underestimated because some of them are incorrectly ascribed to "ill-defined causes of death" or "other heart diseases."

The excess mortality from neoplasms in males is, to our knowledge, unprecedented in the literature. Even though chance alone could be responsible for this result, smoking and alcohol consumption could be confounding factors, given their strong association with illicit drug use.[21,22] Immunosuppression or even HIV infection might also play a role in cancer development, but this hypothesis requires further investigation.

TABLE 2—Cause-specific Mortality among Male Intravenous Drug Users (19 662 person-years)

Cause of Death[a]	OBS	EXP	SMR[b]	95% CI[c]

Suicides (E950–959)	11	1.61	6.8	3.4–12.2
Ill-defined conditions (780–799)	6	0.50	12.1	4.4–26.2
Unknown causes	9	—	—	—

Note. OBS = observed deaths; EXP = expected deaths; SMR = standardized mortality ratio; CI = confidence interval.

[a] Code numbers from the International Classification of Diseases, Ninth Revision, 1975.

[b] SMR were not computed for categories with fewer than two deaths.

[c] Two-tailed test.

In conclusion, our findings indicate that drug abuse is an important cause of mortality in the young in Rome as well as in New York City. Preventive and treatment strategies are urgently needed. □

Acknowledgments

This study was partially supported by grant 429, Second Research Project on AIDS (1989), of Ministero della Sanita'-Istituto Superiore di Sanita'.

The authors thank Drs. Mauro Zaccarelli and Andrea Fiume for their help in collecting the data; Drs. Massimo Arca' and Paola Michelozzi for access to the Latium HIV Surveillance System file; Dr. Susanna Crollari for coding; Dr. Carola Tasco for linkage with the mortalilty files; Dr. Elisabetta Magliola for statistical support; Drs. Andrew Moss and Ernest Drucker for the useful discussion; and Profs. Olav Axelson, David Vlahov, Gerry Stimson, and Don C. Des Jarlais for comments on an earlier version of the manuscript. They also wish to thank Dr. Susan Levenstein for editing the manuscript.

Preliminary results of the study were presented at the First International Conference on the Reduction of Drug Related Harm, Liverpool, UK, April 9-12, 1990, and at the Sixth International Conference on AIDS, San Francisco, Calif., June 20-24, 1990.

Leptospirosis on Kauai: Investigation of a Common Source Waterborne Outbreak

ABSTRACT

During the summer of 1987, a common source waterborne outbreak of leptospirosis occurred on the island of Kauai in the state of Hawaii. Eight leptospirosis cases were identified using the microscopic agglutination test. Methodologic weaknesses in this technique were responsible for the initial missed diagnosis on six of the eight cases. All cases had repeated exposure to the Waimea River. A wide array of animal reservoirs and optimal water conditions may have been factors in this outbreak. *(Am J Public Health.* 1991;81:1310–1312)

Alan R. Katz, MD, MPH, Sally Jo Manea, BSN, and David M. Sasaki, DVM, MPH

Introduction

Since the Hawaii State Department of Health (DOH) began collecting detailed statistics on leptospirosis in the early 1970s, Hawaii has consistently had the highest national annual incidence rate.[1] In 1987, the DOH reported a rate of 2.5 per 100 000 population[2] compared with the national rate of 0.02 per 100 000 population.[3] The following report describes a common source outbreak of leptospirosis from recreational exposure to a fresh water source.

[c] Blood culture positive for serovar *bataviae* (Bataviae serogroup).

The Outbreak

On July 14, 1987, the DOH was notified of three youths hospitalized with suspected leptospirosis. All had repeated exposures to the Waimea River via swimming. The river runs within the lush Waimea Valley on southwestern Kauai. The valley and hills above the river contain cattle, feral goats, pigs, mongooses, and other rodents.

In April 1987, several spontaneous abortions occurred among a herd of 50 cattle pastured adjacent to the swimming area. Sera from the affected animals (9/9) tested positive for *Leptospira interrogans* serovar hardjo (Sejroe serogroup), with microscopic agglutination test (MAT) titers of 1:800 or greater (personal communication Dr. Craig Nishimoto, 1988, oral).

Methods

Case Finding

The three case-patients and their parents were interviewed in an attempt to identify others with recent river exposure. Sixteen males were identified and sampled, including the three hospitalized youths, who swam at this site almost daily between June 14 and July 4, 1987. Sera were sent to the Leptospirosis Reference Laboratory at the US Centers for Disease Control for MAT evaluation.

A "confirmed" case was defined as an individual with recreational exposure to the Waimea River during the abovementioned dates, and positive leptospiral culture or serologic evidence of recent leptospiral infection manifested by a minimal fourfold increase in MAT titers in paired acute and convalescent sera.

Environmental Investigation

Rodents were trapped at and above the exposure site. Water and mud samples downstream from the swimming spot were cultured for pathogenic leptospires. Seroprevalence data from an island-wide leptospirosis cattle survey conducted in late 1987 by the Hawaii State Department of Agriculture (DOA) were evaluated. Ongoing US Geological Survey measurements on the Waimea River near the exposure site were also evaluated.

Results

Eight individuals reported a flu-like illness with onset between July 8 and July 21, 1987. Symptoms included headache 100% (8/8), fever 100% (8/8), chills 87.5% (7/8), nausea 87.5% (7/8), vomiting 75% (6/8), myalgia 62.5% (5/8), diarrhea 50% (4/8), and jaundice 12.5% (1/8). Five of the eight were hospitalized (62.5%), two were treated as outpatients, and one did not seek medical consultation.

Initial MAT paired sera were positive for only two of the eight symptomatic individuals: one demonstrated *L. interrogans* serovar *bataviae* (Bataviae serogroup), and one demonstrated *L. interrogans* serovar *fort bragg* (Autumnalis serogroup). After blood cultures from an individual with a negative MAT grew *L. interrogans* serovar *bangkok* (Australis serogroup), all sera were retested with a new battery of antigens including serovar *australis* (Australis serogroup), which had been missing from the initial antigen battery. The six with initial negative MAT results demonstrated *L. interrogans* serovar *australis* in the retest (Table 1).

Two cases demonstrated positive blood cultures: one with serovar *bangkok* (as noted above) and one with serovar *bataviae*. The eight asymptomatic males were negative serologically for leptospirosis.

Cases ranged in age from 10 to 24 years (median age=14). The duration of symptoms ranged from 2 to 7 days, with a median of 6 days.

Kidney cultures from 14 rodents trapped near the exposure site as well as water and mud samples from the Waimea River were all culture negative for pathogenic leptospires.

The median river flow rate near the exposure site during the outbreak exposure period was 0.31 m^3/second. The 1987 annual mean flow rate at this site was 1.73 m^3/second. On the two dates most closely bracketing the exposure period, the water temperatures were 22°C and 24°C and the pH measurements were 7.10 and 8.20.[4]

The island-wide DOA cattle seroprevalence survey revealed 89 (64%) of 139 cattle positive for *Leptospira* as manifested by MAT titers of 1:100 or greater against one or more serovars. Of 19 cattle bled on the ranch adjacent to the swimming site, 9 were positive: 8 demonstrated serovar *hardjo*, and 1 demonstrated serovar *bataviae*. Four animals geographically removed from the outbreak demonstrated serovar *australis* (personal communication DOA laboratory report, 1988, written).

Intervention

The local radio station, news media, and press reported the outbreak and warned of the potential danger from swimming in the Waimea River. DOH personnel were on site July 15 and 16 to post warning signs and inform swimmers of the potential danger. In addition individuals obtaining camping or conservation permits were given information on leptospirosis. No subsequent leptospirosis cases were reported from the Waimea River, and only one additional case was reported from the entire island of Kauai during the remainder of 1987.

Discussion

The majority of reported leptospirosis cases both nationally and in Hawaii have been sporadic and unrelated.[5,6] However, cluster outbreaks are reported infrequently.[7-10]

The antecedent epizootic of leptospirosis and the high cattle seroprevalence rate would appear to incriminate cattle as the source of this outbreak. However, because serovar *australis* was not identified in cattle pastured adjacent to the exposure site and because the area contains many potential animal reservoirs, this outbreak may be unrelated to cattle. The small number of feral rodents sampled does not justify exclusion from the analysis.

Optimal water conditions for the survivability of waterborne leptospires—a neutral or slightly alkaline pH[11,12] and temperature of 22°C or higher[13]—were documented in the Waimea River around the outbreak exposure period. Decreased flow rates may have allowed concentration of waterborne *Leptospira*.[10,14] Although river water and mud samples were culture negative, the isolation of pathogenic *Leptospira* by direct culture from soil and natural waters is not routinely done and is generally unsuccessful.[15,16]

Although the MAT is considered a reference test for serological diagnosis of leptospirosis,[17] a negative result does not rule out infection because the patient may be infected with a serotype absent from the battery of testing antigens.[17] This phenomenon was responsible for the initial false negative results on six of eight cases in the present outbreak because serovar *australis* was absent from the testing battery. In addition, the MAT is only partially serovar specific. Cross-reactivity is well documented between serovars in the same serogroup as well as related serovars from different serogroups.[17] This explains the confirmed case with positive blood cultures for serovar *bangkok* but MAT results showing the presumptive presence of serovar *australis*.

Through this experience, we learned that sera from individuals infected with serovar *australis* may not cross-react with antigens from the other serogroups and serovars routinely used in the MAT. To optimize the MAT as a diagnostic tool, the testing battery should include antigens from all leptospiral serovars known to be geographically enzootic. ☐

Acknowledgments

Grateful acknowledgment is given to Hal Eichelberger, State of Hawaii Department of Health (Kauai), and Dr. Henri Minette, State of Hawaii Department of Health, for their valuable assistance in the investigation and reporting of this outbreak.

Timeliness of National Reporting of Communicable Diseases: The Experience of the National Electronic Telecommunications System for Surveillance

Guthrie Birkhead, MD, MPH, Terence L. Chorba, MD, MPH, Susan Root, MD, Douglas N. Klaucke, MD, MPH, and Norma J. Gibbs

ABSTRACT

The timeliness of reporting four nationally notifiable diseases was examined using data reported via the National Electronic Telecommunications System for Surveillance. Timeliness of reporting varied by disease (bacterial meningitis: median 20 days; salmonellosis: median 22 days; shigellosis: median 23 days; and hepatitis A: median 33 days) and by state. These findings indicate a need to standardize surveillance definitions and to account for reporting differences between states in interpreting regional disease trends or detecting multistate disease outbreaks. (*Am J Public Health.* 1991;81:1313–1315)

Introduction

The timely reporting of communicable diseases to public health authorities is an important part of public health surveillance.[1,2] Prompt reporting permits rapid case investigation and early detection of epidemics. Timeliness is one of the key attributes by which public health surveillance systems should be judged.[3] However, few studies have examined this factor and its potential impact on disease prevention.[4-7]

We determined the delay in reporting of selected communicable diseases using data transmitted from state health departments (SHDs) via the National Electronic Telecommunications System for Surveillance for publication in the *Morbidity and Mortality Weekly Report.*[8] Our findings have implications both for the interpretation of surveillance data and for the design of surveillance systems.

Methods

The Epidemiologic Surveillance Project (ESP) was initiated by the Centers for Disease Control (CDC) in six states in 1984.[8] The system is now referred to as the National Electronic Telecommunications System for Surveillance (NETSS)[1] and receives weekly reports of 49 nationally notifiable diseases from all state and territorial health departments. For this study, NETSS reports were examined for 1987 when 35 SHDs and the District of Columbia participated in the system. The information available for each report included disease, age, race and ethnicity, sex, and the dates of disease onset and report to CDC.

The reporting delay was calculated as the difference in days between date of disease onset and data of report to CDC. Reporting delay was examined for salmonellosis, shigellosis, hepatitis A, and bacterial meningitis (predominantly due to *Neisseria meningitidis* and *Haemophilus influenzae* type B). These diseases were chosen because each may occur in epidemic form so each case report warrants a prompt investigation, and because the diagnosis of each is confirmed by laboratory findings. Reports were analyzed only for states providing the date of disease onset for at least 70% of NETSS cases (Table 1).

Results

The delay in reporting varied markedly by type of disease (Table 1 and Figure 1). The median reporting time ranged from 20 days for bacterial meningitis to 33 days for hepatitis A. More than 75% of reports were made within 8 weeks of disease onset for all diseases. Timeliness of reporting did not differ by the age and race/ethnicity of the patient or by month of disease onset (data not shown). Median reporting delays for salmonellosis and shigellosis varied widely by state, from as little as 4 days for one state to over 8 weeks for another (Figure 2a). The distribution of reporting delays in two states with different patterns in reporting is illustrated in Figure 2b.

Discussion

A principal purpose of public health surveillance of infectious diseases is to prompt public health action in response to changes in disease occurrence.[2] The time-

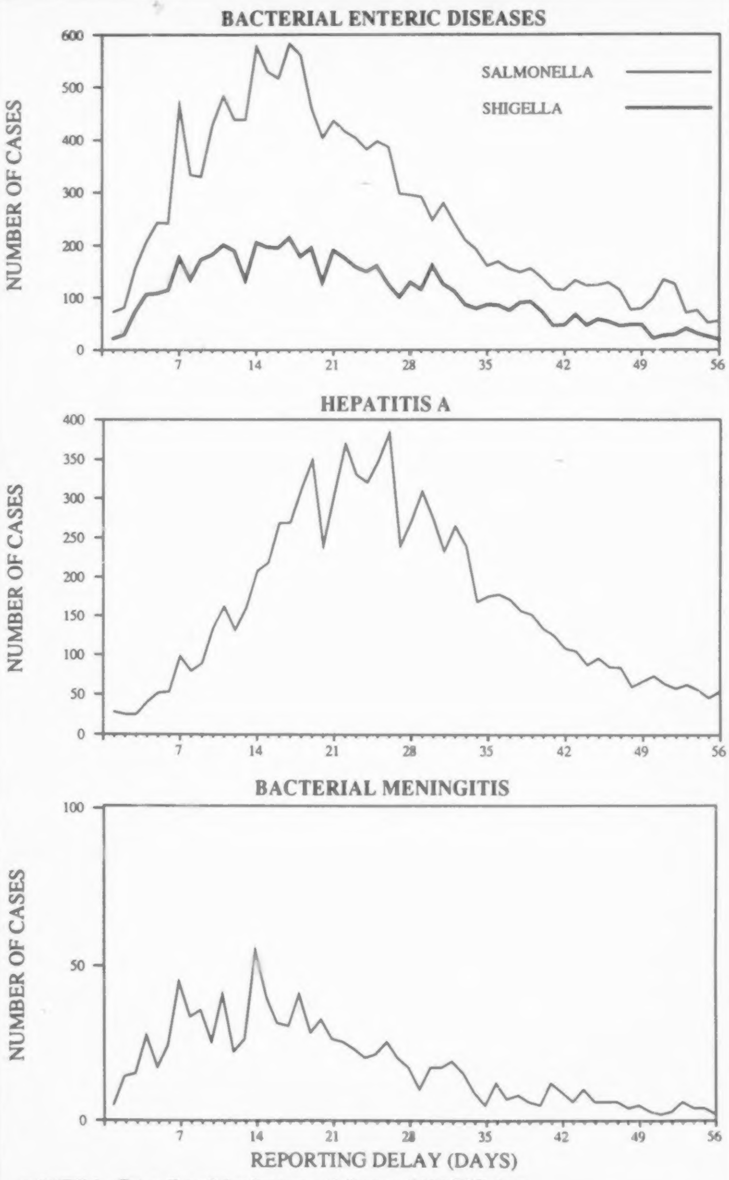

FIGURE 1—Reporting delay by type of disease 1987 ESP data.

liness of reporting is a key element in ensuring that this response is rapid enough to prevent further disease transmission.[1] However, timeliness of reporting and its impact on disease prevention have received little attention in the medical literature.[4–7] We found that the timeliness of reporting to the NETSS system varies widely by type of disease and by state. However, the data available do not allow an evaluation of whether reporting is rapid enough to permit effective disease prevention because timeliness was measured by the report of disease to CDC and immediate preventive action usually takes place at a more local level.

The variability in reporting delay among states may be due to differences among state surveillance systems, including local vs centralized disease reporting, differing statutory requirements for laboratory-based reporting or penalties for failure to report, and differing definitions of disease and of dates of disease onset and disease report. For example, delays in reporting to CDC may be inherent in states in which disease reports go first to county-level health departments before reaching the SHD.

Review of national data does permit detection of regional or multistate disease outbreaks that may be overlooked at the local level. An example of this is the recent recognition of a regional epidemic of *Salmonella* serotype *enteritidis* in the northeastern United States.[9] However, differences in reporting delays between states need to be considered in such an analysis.

Acknowledging the differences in reporting delays by state, the pattern of reporting delays among diseases suggests some factors that may be important in determining reporting time. Reporting of bacterial meningitis was more rapid than for the other diseases studied. This may be due in part to the recognition by physicians and others of the necessity to offer

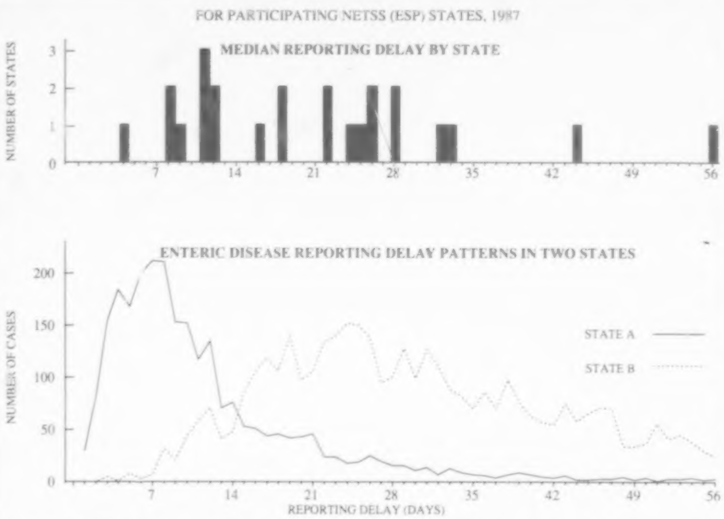

FIGURE 2—Reporting delays from disease onset to report to CDC for enteric disease, by state, for participating National Electronic Telecommunications System for Surveillance States in 1987;
a) = median reporting delay by state;
b) = distribution of reporting delays in two states.

prompt prophylactic treatment with rifampin to close contacts of patients with bacterial meningitis.[10,11] In addition, bacterial meningitis and enteric diseases usually have a more sudden onset and medical care may be sought sooner in the course of disease, allowing more rapid reporting than hepatitis A, which may have a more insidious onset. Finally, bacterial meningitis may be diagnosed from cerebrospinal fluid examination when the patient is first seen by a physician, whereas fecal culture for enteric pathogens and serologic tests for hepatitis A may take several days to complete. This study cannot determine which of these or other factors are most important in determining reporting delay, in part because of the long reporting trail from the physician's office to CDC.

Several areas for improvement in national reporting of surveillance data are highlighted by this analysis. Definitions of date of disease onset and disease report should be standardized. This would parallel recent efforts to standardize disease case definitions and other surveillance system attributes.[3,12,13] For notifiable disease reporting, the date of disease onset is the date of first symptoms attributed to the disease. Date of disease report should be the date of notification of the first-line public health authority responsible for taking immediate preventive action be it town, city, county, or state health department. Health departments should collect the date of disease onset for each reported case. Further studies of the determinants of timely reporting for specific diseases are needed at the local level.

Studies in jurisdictions with unusually short or long reporting times may identify the determinants of the reporting delay. Accounting for inevitable differences in reporting among states in the regional analysis of surveillance data is necessary to take full advantage of national surveillance data for detection of regional or multistate outbreaks. □

The Association between Congenital Syphilis and Cocaine/Crack Use in New York City: A Case-Control Study

Michele S. Zweig Greenberg, MPH, Tejinder Singh, PhD, Mark Htoo, MD, and Stephen Schultz, MD

ABSTRACT

From 1987 to 1989, an epidemic of congenital syphilis was observed in New York City. A case-control study was done to assess the association between various maternal risk factors and congenital syphilis. Independent of the effect of other factors, the odds of being exposed to cocaine were 3.9 times greater among cases than controls (95% confidence interval, 2.8–5.3). This study suggests that the epidemic of congenital syphilis may be related to the increase in cocaine/crack use among delivering mothers. (*Am J Public Health.* 1991;81:1316–1318)

Introduction

The current epidemic of primary and secondary syphilis among women in New York City (NYC) has been characterized by a doubling in the number of cases between 1985 and 1989[1,2] and has contributed to a secondary epidemic of congenital syphilis. Although fewer than 50 congenital syphilis cases per year were reported to the NYC Department of Health (DOH) between 1980 and 1986, 1017 cases were reported in 1989.[2] During this same period, the proportion of delivering mothers in NYC who reported use of cocaine/crack during pregnancy increased dramatically from 1.0 per 1000 live births to 23 per 1000 live births[3] (Figure 1). Because an association between sexually transmitted diseases and cocaine/crack use had been suggested previously,[4–10] we conducted a case-control study to assess the relationship between various maternal risk factors and congenital syphilis in NYC.

Methods

Congenital syphilis is a reportable disease in NYC, and the NYC DOH maintains a registry of all cases reported from physicians, clinics, and hospitals that meet the revised Centers for Disease Control (CDC) criteria for definite or compatible cases.[11] Additionally, the DOH maintains a birth certificate registry that contains information on all babies born in NYC and on selected characteristics of their mothers.

In the case-control study, all babies reported with congenital syphilis in 1989 were identified from the congenital syphilis registry, and the birth certificate registry was then reviewed to locate their birth certificates. All congenital syphilis babies with available birth certificates were defined as cases. The next two babies born without congenital syphilis on the same day as each case were selected as controls. Cases and controls were also matched on race and hospital of birth. If controls could not be selected on the same date of birth as a case, the subsequent day's births were reviewed until an appropriate control was located. For each of the 14 twin case sets, two controls were selected. All information collected on the babies (race, gestational age, and birth weight) and on their mothers (use of cocaine/crack, heroin, marijuana, methadone, and alcohol; level of prenatal care; age; marital status; level of education; and insurance status) was obtained from the babies' birth certificates.

A bivariate analysis was done to compare cases and controls for each baby and maternal characteristic. The strength of association was evaluated by the odds ratio with 95% confidence intervals; statistical significance was set at the $P < .05$ level. Correlations between variables were examined. Conditional logistic regression analysis was performed to assess the independent association of each of the maternal characteristics with congenital syphilis. Data were analyzed using Statistical Analysis System (SAS) version 5.18.[12]

Results

Of the 987 babies born in NYC listed on the congenital syphilis registry as of March 1990, there were 72 without available birth certificates, 32 stillbirths, and 1 with no available controls. Birth certificates were occasionally not located because of discrepancies in the legal names of the children between the birth certificate and congenital syphilis registries. Of

This paper was submitted to the journal October 23, 1990, and accepted with revisions May 7, 1991.

the remaining 882 eligible babies, 881 were compatible cases of syphilis and 1 was a definite case.

Cases and controls were matched on race and included non-Hispanic blacks (73%), Hispanics (22%), Whites (4%), and others or unknown (1%). In the bivariate analysis (Table 1), cases had a significantly lower mean birth weight and gestational age than controls (both $Ps < .001$). Cases were statistically more likely to use cocaine/crack, alcohol, or other drugs; have no prenatal care; be single; and have less than a high school education (all $Ps < .001$). Cocaine/crack use was significantly correlated with alcohol use and being unmarried, and prenatal care was correlated with education (correlation coefficients of .35524, .1988, and .06817, respectively, all $Ps < .001$).

Independent of the effect of other factors, the odds of being exposed to cocaine were 3.9 times greater among cases than among controls (Table 2). Other factors significantly associated with congenital syphilis were being unmarried, alcohol use, number of prenatal visits, and having less than a high school education.

Discussion

In this investigation, a strong association was found between congenital syphilis and maternal cocaine/crack use. Moreover, the increase in congenital syphilis cases in NYC since 1985 was temporally related to an increase in cocaine/crack use (Figure 1), whereas the use of alcohol and other drugs remained relatively stable during this period.[3]

Several limitations must be considered in interpreting these data. Underreporting may be a serious problem in examining congenital syphilis in NYC.[13] Drug use information tends to be based on self-reports, and collection of information on the birth certificate is not standardized throughout hospitals. Although the possibility exists that drug histories were more actively pursued among mothers of babies with congenital syphilis, questioning for drug usage is a routine part of medical history-taking done immediately after birth and well before syphilis serologic results are available.

Maternal cocaine/crack use might contribute to the occurrence of congenital syphilis in a variety of ways. Cocaine/crack use might increase the frequency of sexual activity because of the exchange of sex for drugs, or might lead to an increase in unprotected sexual activity.

No. of prenatal visits	−0.098	0.9[a]	0.88–0.93
Less than high school education	0.298	1.3	1.1–1.7

[a]When entered as a continuous variable, with each decreasing prenatal visit, the odds of being a case are increased by 1.1.

Cocaine/crack use could also lead to a decreased use of prenatal care, thereby causing missed opportunities for the detection and treatment of syphilis (38% of case mothers who used cocaine/crack had no prenatal care). The lower socioeconomic status of cocaine/crack-using mothers could be associated with a decreased availability of health services for this population, or with inadequate services. Among women who gave birth to babies with congenital syphilis in NYC who were reported in 1989 and who were documented to have received prenatal care, only a small proportion were documented to have received treatment for syphilis during their pregnancy.[14] Since so few delivering women received treatment for syphilis, treatment failure is probably not an important factor in the increase of congenital syphilis cases.

The provision of accessible and adequate prenatal health care, along with education targeted to women who engage in high-risk sexual activities, is needed to confront the epidemic of congenital syphilis in NYC. ☐

Human Papillomavirus, Gonorrhea, Syphilis, and Cervical Dysplasia in Jailed Women

Nina A. Bickell, MD, MPH, Sten H. Vermund, MD, PhD, Michelle Holmes, MD, MPH, Steven Safyer, MD, and Robert D. Burk, MD

ABSTRACT

We assessed the prevalence of human papillomavirus (HPV) by cervicovaginal lavage and Southern blot and inquired about behavioral risk factors for cervical disease and sexually transmitted diseases by interview in 114 female detainees at a large New York City jail. Of the women screened, 8% had abnormal Pap smears, 35% had HPV, 7% had gonorrhea, and 22% had serologic syphilis. Given the high rates of HPV infection and cervical cytology, Pap smears should be a routine intake procedure for incarcerated women. (*Am J Public Health.* 1991;81:1318–1320)

Introduction

Prisoners have a high prevalence of drug use, psychiatric disorders, trauma, alcohol abuse, and chronic medical conditions such as respiratory diseases and hypertension.[1,2] The number of incarcerated women in the U.S. increased 53% between 1983 and 1987.[3] At our study site the number of female prisoners has more than doubled in the last 5 years (*SS:unpublished data*).

Prevalence rates as high as 10% for cervical carcinoma in situ, 16% for syphilis, and 5% for gonorrhea have been reported in incarcerated adult women.[4–7] No studies of human papillomavirus (HPV) have been published. Because prisoners have high rates of drug use and prostitution,[3] many are likely to have been exposed to the human immunodeficiency virus (HIV) through these routes.[8] Women

with HIV may have higher risk of HPV-associated cervical cytologic abnormalities.[9]

We undertook a cross-sectional study of the prevalence of HPV, gonorrhea, syphilis, and cervical cytology in imprisoned women, examined selected behavioral risk factors for HPV and other sexually transmitted diseases (STDs), and looked for any association of HPV with cervical abnormalities in this population.

Methods

All female detainees at the New York City Correctional Institute for Women undergo an intake examination at the Montefiore Medical Center/Rikers Island Health Service, which provides comprehensive health care to the Rikers Island Jail complex on a contractual basis with the New York City Department of Health. During four nonsuccessive weeks in 1988, eligible female detainees were asked to participate in this study. Eligibility criteria included age less than 50 years, ability to speak English, an intact uterine cervix, history of heterosexual relations, and competency to give informed consent.

The usual medical intake evaluation includes standardized medical history and a physical including pelvic exam and laboratory tests for TB, syphilis, gonorrhea, pregnancy, and a Pap smear. Those who agreed to participate also received a structured interview before the usual intake and cervicovaginal lavage for HPV.[10] The structured interview elicited additional information about sexual and medical histories. Demographic data of participants and nonparticipants were abstracted from the standardized prison medical charts.

All lab analyses were conducted in a blinded fashion. For analytic purposes, normal Pap smears and those showing only atypia with inflammation were considered "no significant pathology"; those classified with atypia and mild dysplasia, or Class III or IV, were considered abnormal in accordance with the Bethesda cytologic classification system.[11] Syphilis serology was evaluated by rapid plasma reagent tests and, if positive, by fluorescent treponemal antibody (FTA) tests. *Neisseria gonorrhoeae* samples were obtained from the endocervix with a cotton swab and cultured on Thayer Martin plates. HPV DNA was extracted from exfoliated cervicovaginal cells collected by lavage. DNA was digested with a *Pst 1* and resultant DNA fragments were separated by gel electrophoresis. HPV DNA was detected by Southern blot analysis with a mixed probe containing radiolabelled HPV 11, 16, 18, and 31 DNA initially under low stringency and following hybridization, under moderate stringency conditions according to techniques previously published.[10] Statistical calculations included odds ratios (ORs) and Mantel-Haenszel OR_{MH} to measure strength of association.

TABLE 1—Odds Ratios (OR) of HPV Infection and Condom Use among Women with Greater Numbers of Sexual Partners in the Previous Year

Partners, y (n)	OR of Condom Use (95% CI)	OR of HPV Infection (95% CI)
0–1 (54)[a]	1.0	1.0
2–5 (34)	4.1 (0.66–26.1)	1.1 (0.4–2.9)
6–24 (14)	23.7 (6.1–92.1)	2.7 (0.8–9.6)
≥25 (11)	61.5 (13.5–280.3)	1.5 (0.4–5.6)

[a] 0–1 partners = referent group.

Note. ORs are age adjusted; CI = confidence interval; Among women with 25 or more partners in the last year, 73% used condoms and 36% were infected with HPV. Among women with 6–24 partners in the last year, 50% used condoms and 57% were infected with HPV.

Results

Of 145 detainees, 130 met inclusion criteria, and 114 (88% of eligible women) agreed to participate. The most common reason given for refusal was belief that they were not infected; the most common reason for exclusion was a history of hysterectomy. Participants' (N=114) average age was 26.6 years (standard deviation [SD] ± 6.2 years); 53% were Black, 30% Hispanic, and 17% White. Nonparticipants' (N=16) average age was 27.2 years (SD ± 6.8 years); 62% were Black, 25% Hispanic, and 13% White. Sixty-eight percent of the women acknowledged use of some drug, 53% admitted to habitual use of cocaine, and 99% smoked cigarettes.

The median number of reported sexual partners in the last year was 1 (range = 0–2500). Fifty-six percent of the women stated they knew their sexual partners had other sexual partners. The mean age at first coitus was 15 years. Forty women (35%) practiced contraception: 32 used condoms, 5 had tubal ligations, 2 used IUDs and 1 used contraceptive sponges. None used oral contraceptives. Of women using condoms, 80% used them "most" or "all the time." A trend of increased condom use was observed among women with greater numbers of sexual partners (Table 1).

STDs were common: 7% of the women (8/111, 3 missing) had positive gonorrhea cultures, and 22% (24/108, 6 missing) had positive FTA. HPV was the most prevalent STD: 35% of the participants (40/114) were infected.

Pap smears were abnormal in 9% of the women (9/104, 10 missing). There were no cases of invasive cervical cancer. Five of nine women with abnormal Pap smears (56%) were infected with HPV compared to 30 of 95 (32%) women without significant Pap smear pathology (OR = 2.7, 95% confidence interval [CI] = 0.7–10.4). HPV type was not associated with Pap smear abnormality (*R.D. Burk; unpublished data*). The common HPV type prevalence rates were 28% types 16 and 18, 10% type 42, 2% types 6 and 11, and 35% "related" types. Younger women (≤25 years) were more frequently HPV infected (OR = 2.0, 95% CI = 0.9–4.5) and were more likely than older women to have had 2 to 24 sexual partners in the previous year (OR = 2.4, 95% CI = 1.01–5.8). There was an unstable relationship between age and HPV infection when number of sexual partners was controlled for (OR_{MH} = 1.8, 95% CI = 0.8–4.1).

Discussion

In 1988, the typical female detainee at Rikers Island was a woman in her mid-20s who engaged in multiple potentially harmful behaviors, including cigarette smoking, cocaine use, sexual activity by age 15, more than one sexual partner in the last year, and low frequency of condom use. The prevalence of STDs and abnormal Pap smears among the women inmates is of a magnitude similar to that of other studies in young inner city and prison women.[12–14] The marked frequency of condom use in highly sexually active women is probably associated with prostitution. The high HPV prevalence may be related to sensitive cell sampling and DNA detection methods.[15] Although this study did not assess incidence through repeated testing, such studies would be desirable.[16]

The majority of these women did not practice safe sex; 72% had not used condoms. These rates of condom use are similar to those reported among juvenile detainees.[13] High STD rates and low use of barrier contraception are particularly disturbing given the prisoners' increased risk of infection with HIV[17,18] and the increased risk of HPV-associated cervical cytologic abnormalities in immunocompromised women.[9,19]

These data suggest the need for universal Pap smear and STD screening of women in prisons and jails, careful follow-up of women with abnormal Pap smears and those who may be HIV positive, and health education for barrier contraception and STD prevention. ☐

Acknowledgments

This research received approval from the Institutional Review Board (IRB) for Human Subjects for the Montefiore Hospital Medical Center and the IRB of the New York City Department of Health. Both IRBs had inmate advocate representation and met federal guidelines for research in jails and prisons. Dr. J.A. Earp provided useful editorial advice. Ms. Carol Spitzer assisted with DNA analyses. Drs. Lutz Gissmann, Harald zur Hausen, and Attila Lorincz provided molecular probes.

This paper was presented in part at the 1990 Southern Regional Meeting of the Society for General Internal Medicine.

Self-disclosure of HIV Infection to Sexual Partners

Gary Marks, PhD, Jean L. Richardson, DrPH, and Norma Maldonado, BA

ABSTRACT

Self-disclosure of HIV infection to current sexual partners was examined in 138 seropositive men, mostly lower income Hispanics, from Los Angeles. Forty-five percent had been sexually active since learning their serostatus. Of these, 52% had kept their infection secret from one or more partners. The likelihood of disclosure decreased in direct proportion to the number of partners. Nondisclosure occurred in conjunction with unprotected receptive and insertive anal intercourse. Potential factors promoting nondisclosure are discussed. (*Am J Public Health*. 1991; 81:1321–1323)

Introduction

Individuals who are aware they are infected with the human immunodeficiency virus (HIV) and who engage in sexual relations have a social and legal responsibility to disclose their infection to their partners.[1–3] Withholding this information increases the potential for HIV transmission because it creates a situation in which unsafe sexual activity is more likely to occur. Should a partner become infected, he or she may unknowingly infect others. This chain of events suggests that nondisclosure of HIV infection to sexual partners may be an important cause of the continuing HIV epidemic.

Little is known about the prevalence of this behavior. Studies have examined intentions to inform partners among individuals who had not been tested for HIV[4] or had not yet received test results.[5] Two studies have focused on HIV-infected individuals. Of 25 seropositive women, only 52% had disclosed their infection to all sexual partners since diagnosis.[6] One hundred and seven homosexual men informed only 31% of their new sexual partners.[7] We report findings of an ongoing study of self-disclosure in relation to the specific sexual activities performed.

Methods

Adult men who have tested seropositive for HIV in the previous 18 months were recruited for study at a public HIV clinic located in a predominantly Hispanic section of Los Angeles. Study candidates were from any ethnic group, spoke English or Spanish, and were 18 years of age or older.

Recruitment was conducted in the waiting area of the clinic by a bilingual Hispanic woman. Of the men approached, 96% agreed to participate. Each subject completed a self-administered confidential questionnaire in a private section of the waiting area. A four-digit numerical code, uniquely derived by each subject, was used as identification.

Sexual activity and disclosure were measured with a matrix checklist thoroughly explained to each subject. Instructions requested subjects to think of all partners since testing seropositive, including intimate lovers, casual partners, and spouse if married. For each partner, subjects checked the activities that occurred[8,9] and indicated whether they had revealed their HIV infection before the activity (yes = 1; no = 0) and whether the partner was known to be infected with HIV (yes = 1; no or don't know = 0). Subjects who had not had any sexual relations during this time period checked a box at the top of the checklist.

Results

The sample consisted of 138 men (104 Hispanics, 83% of whom used a Spanish language questionnaire; 21 non-Hispanic Whites; 11 Blacks; and 2 Asians). Ninety-one percent identified themselves as homosexual or bisexual. Overall, 13% reported ever injecting a nonprescription drug and 2% reported injecting drugs since they tested seropositive. Seventy percent had an annual income under $10 000.

Sixty-one percent were asymptomatic or had minimal symptoms short of AIDS-Related Complex (ARC), 16% had ARC, and 23% had AIDS.[10] Seventy-five percent had tested HIV seropositive within the previous 8 months.

Sixty-two of the 138 men (45%) had been sexually active (other than kissing) since learning their serostatus. Of these 62, 4 were deleted from the disclosure analysis due to missing data on relevant questionnaire items. Thirty out of 58 men (52%) kept their infection secret from one or more partners. Disclosure did not differ significantly by ethnicity (i.e., Hispanic vs non-Hispanic).

Of the men who had only 1 sexual partner since diagnosis (n = 36), 69% disclosed their serostatus to that partner. Among those with 2 to 4 partners (n = 11),

TABLE 1—Sexual Activity since Testing HIV Seropositive and Disclosure of HIV Infection to Partners

	Nondisclosure				Disclosure			
	All Partners		HIV-Neg. Partners		All Partners		HIV-Neg. Partners	
Sexual Activity	Ss	Ps	Ss	Ps	Ss	Ps	Ss	Ps
Anal insertive/NC	10	13	10	13	12	13	5	5
Anal insertive/C	12	23	12	22	12	15	9	12
Anal receptive/NC	17	41	17	41	8	8	3	3
Anal receptive/C	16	51	16	48	13	15	10	12
Oral insertive/NC	17	40	14	35	12	15	6	8
Oral insertive/C	5	9	5	9	5	5	4	4
Oral receptive/NC	21	71	21	69	14	15	8	8
Oral receptive/C	7	26	7	26	4	4	4	4
Vaginal insertive/NC	3	3	2	2	0	0	0	0
Vaginal insertive/C	5	15	5	15	4	4	4	4

Note: Ss = no. of subjects; Ps = no. of partners; NC = without condom; C = with condom. Sixty-two men reported sexual activity other than kissing since testing seropositive. Four men from this subgroup had missing data on disclosure and partners' HIV status and were deleted from the analysis. Thus, the entries can be evaluated against 58 men who had sexual relations since testing seropositive and provided full data or against the total sample of 138 men.

36% disclosed to at least 1 partner. Among those with 5 or more partners (n = 11), only 18% disclosed to at least 1 partner. This highly significant trend ($(\chi^2) = 9.50$, $P < .01$) indicates that the likelihood of disclosure decreased in direct proportion to the number of partners.

Table 1 displays, for each sexual activity, the total number of subjects, total number of partners, and number of partners presumed to be seronegative at the time of the activity. Information is provided separately for partners to whom subjects disclosed and those to whom subjects did not disclose. Ten subjects (17% of the sexually active) engaged in insertive anal intercourse without using a condom and without disclosing to 13 seronegative partners. Seventeen men (29% of the sexually active) engaged in unprotected receptive anal intercourse without disclosing to 41 seronegative partners. The higher prevalence of receptive than insertive anal intercourse is consistent with a study of HIV-infected homosexual White men from Boston.[11] Both activities are risk factors for transmitting the virus.[12]

In Table 1, the difference between the total number of partners and the number of seronegative partners represents the number of seropositive partners. This difference was larger for informed than uninformed partners, indicating that subjects tended to reveal their infection to those known to be seropositive. When the activity involved insertive or receptive anal intercourse, disclosure to seropositive partners generally occurred in combination with unprotected contact, whereas disclosure to seronegative partners generally occurred in combination with protected contact.

Finally, we examined whether the gender of the partner was associated with disclosure among the bisexual men. Because the activity checklist did not explicitly ask subjects to indicate partner gender, we compared nondisclosure rates for vaginal intercourse (female partners) with nondisclosure rates for receptive anal intercourse (male partners). No significant differences were found.

Discussion

In a sample consisting primarily of lower socioeconomic homosexual/bisexual Hispanic men, we found a relatively high prevalence of nondisclosure of HIV infection to current sexual partners in combination with unsafe sexual activity. For this sample, nondisclosure was not due entirely to lack of knowledge about sexual transmission of HIV. Ninety-four percent of the subjects were aware that they could infect others through unprotected sexual intercourse. Use of alcohol or other nonintravenous drugs before sexual relations, as well as attitudes about social responsibility, may have been factors, although we do not have confirmatory information.

The restricted nature of our sample precludes any wide generalization of the results. Additional studies of Whites, Blacks, Hispanics, and other minority groups of varying socioeconomic levels are needed before a more refined picture can be obtained. Investigation of factors promoting nondisclosure would be immensely valuable for counseling and educational purposes. ☐

Immunoglobulins and Growth Parameters at Birth of Infants Born to HIV Seropositive and Seronegative Women

Arlene Butz, CPNP, ScD, Nancy Hutton, MD, and Elaine Larson, RN, PhD

ABSTRACT

Health characteristics of neonates born to human immunodeficiency virus (HIV) seropositive (n=63) and HIV seronegative (n=57) women were compared. No significant differences were found between the two infant groups for sociodemographic characteristics, mode of delivery, Apgar scores, gestational age, growth parameters, or immunoglobulin levels. Furthermore, no differences were detected in a subgroup of infants later confirmed to have HIV infection (class P-2). Maternal HIV infection does not appear to affect newborn health characteristics. (*Am J Public Health.* 1991;81:1323–1326)

Introduction

As of July 1990, 2464 cases of acquired immunodeficiency syndrome (AIDS) had been identified in patients under 13 years of age,[1] with 78% to 80% presumed to have contracted human immunodeficiency (HIV) infection by vertical transmission.[2,3] The efficiency of virus transmission from an HIV-infected mother to infant is reported to be 13% to 50%.[4–6] Early diagnosis of infection is difficult because transplacentally transmitted anti-HIV antibodies are present in all infants of HIV-seropositive mothers and persist up to 15 months of age or longer.[4,7]

Elevated serum immunoglobulin (IgG, IgM, and IgA) levels are a hallmark of pediatric HIV infection, often developing prior to other laboratory abnormalities such as a decrease in T helper (CD4) cells.[8,9] Birth weight, head circumference, and gestational age have been inconsistently reported to be decreased in infants with perinatal HIV infection.[10–13]

This ongoing prospective study followed a cohort of infants born to mothers at risk for HIV infection to compare the health and growth characteristics of HIV-infected and HIV-noninfected infants from comparable risk strata. The analysis of birth characteristics, specifically growth parameters and immunoglobulins, is presented here.

Methods

All infants born to HIV-seropositive women delivering at an inner-city hospital were eligible for study. An equal number of HIV-seronegative women with acknowledged risk behaviors (intravenous [IV] drug use, sexual contact with IV drug user) were enrolled as control subjects. HIV counseling and testing are offered to all obstetric patients who deliver at this hospital. For most mothers, maternal risk status was determined prenatally by standardized questionnaire and HIV testing performed for consenting women. Newborn HIV testing was offered to unregistered mothers who acknowledged HIV risk factors. Overall there is a 5% seropositivity and 10% refusal rate in this population.[14] In order to examine differences in appropriate intrauterine growth independent of prematurity, infants with less than 34 weeks gestation were excluded.

Each infant's blood was tested within 2 weeks of birth (usually within 24 hours of birth) for HIV antibody and quantitative immunoglobulins, and medical records were reviewed. Weight, length, head circumference, and gestational age were measured in a standardized fashion immediately postdelivery by designated nursery staff. Weight and gestational age by Ballard score[15] was used to classify newborns for intrauterine growth:[16] small, appropriate, or large for gestational age (SGA, AGA, LGA, respectively).

IgG and IgM quantitation was performed by nephelometry (a light scattering technique). Radioimmunodiffusion was used to quantitate IgA levels. The presence of HIV antibody was determined by ELISA (Genetics System, Seattle, Wash) and confirmed by Western blot (DuPont, Wilmington, Del).

Results

Between August 4, 1988, and June 1, 1990, 120 of 127 mothers (95%) agreed to enroll their infant in the study, including 10 infants born to unregistered mothers (5 HIV positive and 5 HIV negative). Sixty-three infants (52.5%) were born to HIV-seropositive mothers, 91% were Black, and 49% were male (Table 1). Maternal substance abuse was the predominant

IgA	2 ± 2		0–13	

[a] Data from Meites S.[16]
[b] Data from Fosarelli et al.[17]

HIV risk factor (75%). Prenatal drug exposure occurred in 84% of infants born to HIV-negative women vs 67% of infants born to HIV-positive women (*P*=.06). Type of delivery (85% vaginal) was not statistically associated with seropositivity. Prenatal sexually transmitted disease (gonorrhea and syphilis) exposure was not significant between HIV-positive and HIV-negative infants (*P*=.24). There was no difference between groups for mean Apgar scores at 1 and 5 minutes or mean gestational age (Table 1).

Fourteen infants (six HIV-positive) were SGA. The majority of these infants (79%) were born to prenatally substance-abusing mothers (HIV-negative =7/8, HIV-positive =4/6; Fisher's exact, *P*=.39). For all infants, there was no significant difference between SGA and non-SGA infants for prenatal drug use (Fisher's exact, *P*=.54).

There was no statistically significant difference for any growth parameter between HIV-positive and HIV-negative infants (Table 2). Mean birth weight for HIV-positive infants was 2811 g and 2878 g for HIV-negative infants (range for all infants: 1585–4586 g, *P*=.51). Three infants (one HIV-positive, two HIV-negative) had a birth weight between 1500 g and 1800 g.

Mean differences for quantitative IgG, IgM, and IgA between the HIV-positive and HIV-negative infants were not statistically significant (Table 3). When mean values for IgG, IgM, and IgA in each group of infants were compared to standardized values previously published[17,18] for a comparable population of Black infants from the same institution,[16] all were within normal limits except for the mean IgM level for HIV-negative infants (13.5 mg/dl), which was slightly lower.

Ten HIV-positive infants developed class P-2 HIV disease[19] during the study period (range of follow-up=9–30 months). Comparison of birth weight, gestational age, and immunoglobulin levels of these 10 HIV-infected infants with remaining HIV-positive infants (P-O, i.e., indeterminate status) and HIV seroreverters (infants born HIV antibody seropositive who reverted to seronegative status by 15–18 months of age) revealed no differences among the three groups (Table 4) with the exception of higher IgA in the HIV reverter group.

Discussion

Our data indicate that in a US urban center with a high prevalence of IV drug use, birth characteristics did not differ between infants born to HIV-positive mothers and HIV-negative mothers with comparable risk. Immunoglobulins were not significantly different between the two groups of infants or between HIV indeterminate, HIV-infected, or HIV seroreverter infants. Elevated immunoglobulin

[b] P-2=symptomatic HIV infection.
[c] P-O=indeterminate status (HIV antibody seropositive at birth, asymptomatic <15 months of age).
[d] Reverters=HIV antibody seropositive at birth and converted to HIV seronegative by 15–18 months of age.
[e] HIV negative=HIV seronegative at birth and remained seronegative (controls).

levels have been found by 5 to 9 months of age in HIV-infected infants.[9,20] We found no retardation in growth that could be attributed to maternal HIV infection when infants with similar environmental exposures were compared. Risk factors for HIV infection were dominated by maternal IV drug use or sexual contact with an IV drug user, comparable to trends for HIV infection in women in Western countries.[21–23] Because screening programs targeted to high-risk women fail to identify a substantial proportion of women with HIV infection[14,24] and prenatal HIV testing is voluntary, it is possible that some HIV-exposed infants were not included in this sample. The sample size achieved was sufficient to detect clinically significant differences in weight (265 g), length (1.43 cm), and head circumference (1.38 cm) between HIV-positive and HIV-negative groups with a power of 80%.[25]

Neither set of birth characteristics, growth parameters, or immunoglobulins distinguishes HIV-infected infants from comparable risk noninfected infants at birth. All infants born to HIV-risk women require vigilant pediatric follow-up for early diagnosis of true HIV infection. ☐

The Impact of HIV on the Usefulness of Sputum Smears for the Diagnosis of Tuberculosis

Richard Long, MD, Marcella Scalcini, MD, MPH, Jure Manfreda, MD, Michel Jean-Baptiste, MD, and Earl Hershfield, MD

ABSTRACT

In a developing country, 289 patients were examined for active pulmonary mycobacterial disease (sputum smear and culture) and HIV infection (serology) to compare the sensitivity and positive predictive value of sputum smears for diagnosing pulmonary tuberculosis in patients with and without antibodies to HIV. Seventy-nine percent of HIV-seronegative vs 66% of HIV-seropositive patients with positive cultures for *Mycobacterium tuberculosis* were smear positive ($P < .05$), and a positive sputum smear predicted the presence of *M. tuberculosis* in 90% of HIV seronegative vs 80% of HIV seropositive patients ($P < .05$). In our opinion, HIV did not significantly compromise the diagnostic utility of the sputum smear. (*Am J Public Health.* 1991;81:1326–1328)

Introduction

The continuing usefulness of sputum smears for the diagnosis of tuberculosis in developing countries has been questioned. In a recent editorial,[1] Pitchenik expressed concern that immunosuppression resulting from human immunodeficiency virus (HIV) type 1 may not only have reduced the sensitivity of the sputum smear by reducing caseation necrosis, and thus the number of acid-fast bacilli in the airway,[2-5] but may also have affected the specificity of the sputum smear by increasing the proportion of patients with nontuberculous mycobacteria.[6] To determine whether HIV has compromised the usefulness of the sputum smear, we compared the sensitivity and positive predictive value of smears for the diagnosis of pulmonary tuberculosis in rural Haitians with and without antibodies to HIV.

Methods

Over a 1-year period beginning March 1988, 323 consecutive rural Haitians presented to a district hospital (Hopital Albert Schweitzer) with suspect pulmonary mycobacterial disease had positive sputum smears for acid-fast bacilli and/or positive cultures for mycobacteria. None had received antituberculous drugs in the preceding 12 months. HIV antibody status was determined in 297 (92%) patients; serum was not available for 4 patients who died shortly after admission and 22 who either refused the test or had already left the facility. Eight HIV-tested children were excluded because the positive culture was from a gastric aspirate and not a sputum specimen. This left a total of 289 (89%) patients for whom results of HIV testing, sputum smear examination, and sputum culture were available.

Two to three fresh, first morning deep cough specimens of sputum were collected from each patient and processed in a manner identical to that reported previously.[7] Standard methods of decontamination, staining, culture, and speciation were applied.[8-11] After obtaining informed consent, serum was collected and tested for antibody to HIV using standard methodology.[12]

Chi-square and Fisher's Exact test were used to compare the sensitivity and positive predictive value of sputum smears for the diagnosis of tuberculosis in HIV-seropositive and HIV-seronegative patients with pulmonary mycobacterial disease.[13]

Results

The 289 study patients ranged in age from 12 to 95 years; 54% were male and 46% female. Table 1 shows that 74 (26%) were HIV seropositive, 222 (77%) smear positive, and 266 (92%) culture positive. Culture was positive for *Mycobacterium tuberculosis* alone in 236, for both *M. tu-*

berculosis and nontuberculous mycobacteria (NTM) in 21, and for NTM alone in 9 patients.

It can be deduced from Table 1, that the sputum smear was significantly ($P<.05$) less likely to be positive for acid-fast bacilli in HIV seropositive (50/74, 68%) than in HIV seronegative (172/215, 80%) patients. Likewise, a sputum culture positive for *M. tuberculosis* was less likely ($P=.05$) to be present in HIV seropositive (61/74, 82%) compared to HIV seronegative patients (196/215, 91%). In contrast, HIV seropositive patients were more likely ($P=.05$) to have sputum cultures positive for an NTM alone (5/74, 7%) than were HIV seronegative patients (4/215, 2%). The proportion with a negative culture was not significantly different between HIV seropositive (8/74, 11%) and seronegative (15/215, 7%) patients.

TABLE 1—Sputum Smear and Culture Status of HIV Seropositive and Seronegative Haitians with Pulmonary Mycobacterial Disease

	HIV Positive (n=74)		HIV Negative (n=215)	
Culture	Smear +	Smear −	Smear +	Smear −
TB	37	18	143	38
TB and NTM	3	3	12	3
NTM	2	3	2	2
Negative	8	0	15	0
Total	50	24	172	43

Note. HIV = human immunodeficiency virus type 1; TB = *M. tuberculosis*; NTM = nontuberculous mycobacteria; + = positive; − = negative.

TABLE 2—Species of NTM Isolated from HIV Seropositive and Seronegative Haitians with Pulmonary Mycobacterial Disease

	HIV Positive				HIV Negative				
	Smear +		Smear −		Smear +		Smear −		
	TB Culture		TB Culture		TB Culture		TB Culture		
NTM	+	−	+	−	+	−	+	−	Total
M. scrofulaceum	2	2	1	1	6		1		13
M. gordonae					4		2		6
M. fortuitum				1[a]		2[b]		2[a]	5
M. flavescens			1		1				2
M. avium complex					1				1
M. vaccae			1						1
M. avium complex M. gordonae	1								1
M. gordonae and *M. fortuitum*				1[a]					1
Total	3	2	3	3	12	2	3	2	30

Note. HIV = human immunodeficiency virus type 1; NTM = nontuberculous mycobacteria; TB = *M. tuberculosis*; + = positive; − = negative.

[a] Biovariant *peregrinum*.

[b] Biovariant *fortuitum*.

The sensitivity of a positive acid-fast smear to identify subjects with a positive *M. tuberculosis* culture was significantly greater in HIV seronegatives than in HIV seropositives. The sensitivity in HIV seronegatives was 79% (155/196) in comparison to 66% (40/61) in HIV seropositives. In addition, a positive sputum smear predicted the presence of *M. tuberculosis* in 80% (40/50) of HIV seropositive patients and 90% (155/172) of HIV seronegative patients, a difference that was also statistically significant ($P<.05$). Neither the sensitivity nor the positive predictive value varied by age or sex.

The species of NTM isolated from 30 patients are shown in Table 2. *M. scrofulaceum* was the most common NTM isolated (13/30, 43%). In 10 instances it was isolated together with *M. tuberculosis* and in 3 it was the only isolate. All of the latter isolates were from HIV seropositive patients. *M. fortuitum* was the next most common NTM isolated (6/30, 20%). In each instance (except one where it was isolated together with *M. gordonae*) it was the only isolate, accounting for 67% (6/9) of the patients in which an NTM alone was isolated. Of the 6 patients from whom *M. fortuitum* was isolated, 2 were HIV seropositive.

Discussion

Particularly in developing countries, where resources for mycobacterial culture are often not available, acid-fast smears are relied on to diagnose tuberculosis. Before the AIDS epidemic the sensitivity of a positive sputum smear was relatively low, but the positive predictive value was high.[14] A patient with a positive smear was almost certain to have tuberculosis and was treated accordingly. Whether HIV modifies the sensitivity and positive predictive value of the sputum smear, especially in developing countries where HIV seroprevalence may be high,[15] is not known. In our study of rural Haitians we found small but significant differences in the sensitivity and positive predictive value of sputum smears between HIV seropositive and HIV seronegative pulmonary tuberculosis patients; 79% of HIV seronegative vs 66% of HIV seropositive patients with positive cultures for *M. tuberculosis* were smear positive, and a positive sputum smear predicted the presence of *M. tuberculosis* in 90% of HIV seronegative vs 80% of HIV seropositive patients. In our opinion, these differences are small and do not significantly compromise the usefulness of sputum smears in developing countries such as Haiti, where the prevalence of tuberculous infection is high.[16] Regardless of HIV status, patients with sputum smear positive pulmonary mycobacterial disease should be assumed to have disease caused by *M. tuberculosis* and should be treated accordingly. ☐

Human Exposure to Rabies from Pet Wild Raccoons in South Carolina and West Virginia, 1987 through 1988

Bradley A. Woodruff, MD, MPH, Jeffrey L. Jones, MD, MPH, and Thomas R. Eng, VMD, MPH

ABSTRACT

During 1987 and 1988, exposures to eight pet wild raccoons in South Carolina and West Virginia resulted in administration of rabies postexposure prophylaxis to 19 children and 26 adults. All eight raccoons appeared normal at the time of capture, and three had no signs of illness when sacrificed. The direct medical cost resulting from these exposures was $23 714 ($527 per person). Regulations and public education may help decrease this type of rabies exposure. (*Am J Public Health.* 1991;81:1328–1330)

Introduction

Although human rabies deaths in the United States are extremely rare, approximately 18 000 persons per year receive rabies postexposure prophylaxis (CDC, unpublished data). In most southeastern and mid-Atlantic states, including South Carolina and West Virginia, raccoons account for the largest proportion of laboratory-confirmed rabid animals.[1] Most human exposures from rabid raccoons and other wild animals involve animals encountered in the wild, but exposures to rabid wild animals kept as pets have been documented.[2–4] As a result, several health organizations and government agencies recommend that wild animals not be kept as pets, and most states have laws requiring special permits to keep such animals[5]; however these measures may be ineffective. In this report, we describe eight incidents where wild raccoons were captured and kept as pets resulting in potential human exposure to rabies in South Carolina and West Virginia in 1987 and 1988.

Methods

State public health personnel in West Virginia and South Carolina were interviewed regarding incidents of possible human rabies exposure resulting from pet wild raccoons during 1987 and 1988. All reports were further investigated by interviewing exposed persons, physicians, and public health personnel and by reviewing records in state laboratories, physicians' offices, and emergency rooms. Data were available only for persons who received prophylaxis.

Bradley A. Woodruff and Jeffrey L. Jones are with the Epidemiology Program Office of the Centers for Disease Control. Bradley A. Woodruff also is with the West Virginia Department of Health, and Jeffrey L. Jones also is with the South Carolina Department of Health and Environmental Control. Thomas R. Eng is with the Division of Viral and Rickettsial Diseases of the Center for Infectious Diseases.

Requests for reprints should be sent to Bradley A. Woodruff, NCID:DVRD:HB, Mailstop A-33, Centers for Disease Control, 1600 Clifton Road, Atlanta, GA 30333.

This paper was submitted to the journal November 19, 1990, and accepted with revisions April 24, 1991.

Human exposure to rabies was defined as a bite, a scratch, or direct contact with saliva from a laboratory-proven rabid animal. Potential exposure was defined as similar contact with an animal that was not tested.

Direct medical care costs included the cost of rabies immune globulin (RIG) and human diploid cell vaccine (HDCV) and the costs for services provided by hospitals and physicians. Medical costs were calculated from billed amounts. Direct social costs, such as the costs of contact investigations and laboratory testing, and indirect personal costs, such as lost wages and transportation costs, were not included in cost estimates because data were unavailable.

TABLE 1—Summary Data for Eight Incidents of Actual and Potential Human Rabies Exposures from Pet Wild Raccoons, South Carolina (SC) and West Virginia (WV), 1987–1988

	Number of Persons Exposed		Type of Exposure			
State	Child[a]	Adult	Bite	Scratch or Contact with Saliva	Duration of Captivity (months)	Minimum Incubation Period[b] (months)
SC	5	8	7	6	1	1
SC	0	2	1	1	.25	.25
SC	1	0	1	0	?[c]	?[c]
SC	2	2	4	0	1	1
SC	1	1	2	0	12	1.25
WV	7	9	1	14	1	1
WV	0	1	1	0	8	3
WV	3	3	1	4	0.5	0.5
Total	19	26	18	25	3.4 (mean)	1.1 (mean)

[a] ≤15 years of age.

[b] Time between last possible contact with a potentially rabid animal and time of the raccoon's diagnosis of rabies (either onset of signs or date of laboratory testing).

[c] Unknown.

Results

During 1987 and 1988, 8 incidents occurred in South Carolina and West Virginia involving potential or actual human rabies exposure from pet wild raccoons (Table 1). None of the eight raccoons had signs of rabies or behaved abnormally at the time of capture. The median interval between capture and the discovery of rabies was 1 month (range = 7 days to 1 year). The precise incubation period was unknown for these animals; however, minimum incubation periods could be derived from the date of last possible contact with other potentially rabid animals.

Six raccoons were tested for rabies; five were positive and one was reported as "inconclusive." Of the five positive animals, two appeared normal at the time of sacrifice, two died after developing signs of illness, and one died suddenly without signs of illness. Two animals were not tested for rabies: one was shot in the head, making testing impossible, and the other escaped after biting the owner. Of the three animals sacrificed without signs of illness, two were killed only after persons who had been bitten demanded that the animals be tested.

Of the 45 persons receiving prophylaxis, 19 (42%) were children ≤ 15 years of age. Eighteen (40%) persons were bitten, 25 (56%) were scratched or exposed to saliva, and 2 (4%) had no apparent exposure but demanded prophylaxis. All were residents of rural areas.

Five raccoons exposed only members or close friends of a single household. Three raccoons exposed others in the community. In the first such incident, a baby raccoon was passed between two families and handled by many neighborhood children, exposing 16 persons. In the second incident, a rabid raccoon displayed in a store exposed 13 customers and staff. In the third incident, a science teacher encouraged a student to bring his pet raccoon to school; two students in the class required prophylaxis after the raccoon was found to be rabid.

The 45 persons in the 8 incidents received 420 cc of RIG and 225 doses of HDCV at a cost of $21 092. Physician, emergency department, and clinic fees were $2622, for total direct health care costs of $23 714 or $527 per treated person.

Discussion

Keeping wild animals as pets poses a substantial risk of human rabies exposure. No vaccine can prevent rabies infection in such animals, because current rabies vaccines are not licensed for use in wild animals. As in all the incidents described in this report, owners of pet rabid animals are often not aware of their animal's infection because, at the time of capture, the animal may appear completely healthy. In addition, rabies infection in raccoons and other wild animals may have a longer subclinical course than in domestic animals.[6-8] In our series, five of eight animals had incubation periods lasting 1 month or longer. If an animal is infectious for a long period of time, both the number of persons contacting the animal and the likelihood of rabies exposure increase.

On average, a rabid pet wild animal exposes more persons to rabies than a rabid domestic animal or free-living wild animal.[9] This is probably due to longer human contact with pet wild animals than with wild animals in nature, and/or the greater attraction posed by an unusual pet such as a raccoon than is posed by more common domestic animals. In addition, pet wild animals may bite or scratch more than domestic animals, and such behavior may be more readily considered normal, resulting in delayed testing for rabies. As an extreme example of the large numbers of persons who can be exposed to a single animal, one pet rabid raccoon in Florida accounted for the prophylaxis of 172 persons at a cost of more than $64 000.[4] Moreover, many rabies exposures from wild animals may go unrecognized and untreated in children. Most dog bite injuries in this age group are not reported to health professionals[10]; the same may be true of bite injuries from wild animals.

Current legislation or regulation may be insufficient. For example, South Carolina regulations do not forbid keeping wild animals as pets. While West Virginia law allows wild animal adoption only during the hunting season for that particular species and requires a special permit, the owners of the three raccoons in West Virginia reported ignorance of these regulations. Public education is needed regarding the dangers of keeping wild animals as pets and the existence of applicable laws and regulations. Programs should target groups at highest risk, including children and residents of rural areas. ☐

Routine Nutrition Screening Could Prevent Serious Health Problems in the Nation's Elderly, Report Says

A significant percentage of older Americans are at risk of malnutrition which could be detected and prevented through routine, inexpensive nutrition screening and greater attention to nutritional needs, according to a research report released recently.

"This excellent report lends new weight to the proposition that routine nutrition screening and care can help prevent serious illness and keep older Americans healthy and independent," said Representative Edward Roybal (D-Ca), Chair of the House Select Committee on Aging, who joined in releasing the report. "That's not only good for individuals, it's good news for a nation struggling to hold down health care costs."

The report, *Screening Older American's Nutritional Health: Current Practices and Future Possibilities,* was written by Johanna T. Dwyer, DSc, RD, Director of the USDA Frances Stern Nutrition Center at Tufts University in Boston. It is one of the most comprehensive reviews ever undertaken to examine the prevalence of malnutrition and nutrition-related problems among this nation's elderly.

"Using widely accepted criteria, a substantial proportion of older Americans have dietary intakes or diseases which place them at high risk of malnutrition," Dwyer said. "Routine nutrition screening, not only to detect the presence of malnutrition but to identify those at risk of poor nutrition, is the essential first step to improving people's nutritional status and keeping older Americans free living and in good health."

In a Foreword to the Report, Joyce T. Berry, PhD, US Commissioner on Aging, says, "Nutrition is one of many important factors affecting the health and longevity of older persons. For many low-income and minority older Americans it might be the most important."

Representative Ralph Regula (R-OH), a senior minority member of the House Select Committee on Aging, applauded Dwyer's recommendation that "screening for risk factors of malnutrition in older Americans does not need to be—nor should it be—limited to health professionals.

"Dr. Dwyer makes the case convincingly that attention to nutritional status needs to become as routine as taking our temperature or pulse," Regula said.

"The fact that nonmedical professionals and individuals themselves can employ screening techniques represents tremendous potential to keep people healthy without resorting to costly medical treatments," Regula said. "And the cost for a few minutes spent screening in a physician's office as part of a routine check-up could save many times that much in acute or chronic care treatment later."

Research has shown that people suffering from poor nutritional status have longer and more expensive hospital stays, and suffer more major complications when they are ill or injured.

Dwyer's research was commissioned by the Nutrition Screening Initiative, a five-year project focused on nutrition screening and better nutritional care among the nation's older adults.

Canine Seroprevalence and the Distribution of *Ixodes dammini* in an Area of Emerging Lyme Disease

Peter W. Rand, MD, Robert P. Smith, Jr, MD, MPH, and Eleanor H. Lacombe, BS, MT(ASCP)

ABSTRACT

This study evaluates the relative usefulness of canine serosurveys to predict risk of exposure in an area of emerging Lyme disease by comparing the distribution of canine seroprevalence with that of vector ticks. From 16 veterinary clinics throughout the State of Maine, 828 canine sera were obtained during the heartworm-testing months of April and May 1989 and measured for anti-*Borrelia* antibodies by enzyme-linked immunosorbent assay. In the same year, 1605 ticks, including 585 *Ixodes dammini*, were collected from pets, humans, small mammals, and deer. Thirty-six dogs were seropositive, 28 of which had not traveled to endemic areas. Eighty-nine percent of all seropositive dogs were from towns within 20 miles (32 km) of the coast; the great majority lived within 5 miles (8 km) of tidewater (odds ratio = 4.45, $P = .002$). Positivity varied from 17% in a southern coastal clinic to 0% in four northern clinics. Of 585 *I. dammini* identified, all but 5 (99.1%) were also from towns within 20 miles of the coast. Comparison of *I. dammini* submissions with those of another commonly found tick, *Ixodes cookei*, corroborated this predominantly coastal distribution. Canine seropositivity generally coincided with this coastal range. These data predicted areas of risk for human Lyme disease, although the prevalence of reported cases remained low. (*Am J Public Health.* 1991;81:1331–1334)

Introduction

Predicting potential areas of Lyme disease risk poses a difficult challenge for public health personnel, particularly in emerging areas with low case prevalence. Passive surveillance for reported human cases is likely to be both insensitive and of questionable specificity.[1–4] Tick vector distribution surveys based on small mammal trapping, flagging, or examination of deer are labor intensive and do not provide relative estimates of the risk of Lyme disease transmission. On the other hand, given that dogs are at greater risk of exposure than humans,[5] canine anti-*Borrelia* serosurveys offer a promising means for targeting areas for potential human risk.

The tick vector of Lyme disease, *Ixodes dammini*, was first reported in Maine in 1985.[6] Despite its subsequent establishment in coastal areas and the proximity of a hyperendemic community to the south,[7] only six cases of locally acquired Lyme disease had been reported through 1988 (unpublished data, Maine Bureau of Health Epidemiology Program, February 1991). In that year we initiated tick distribution surveys and a canine serosurvey as methods of projecting local risk of infection that might be more sensitive, efficient, timely, and economical than those involving human surveillance.

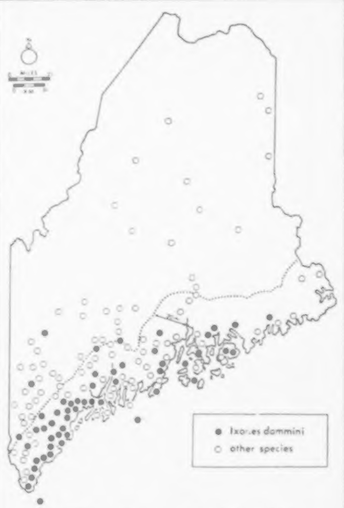

FIGURE 2—Towns of origin of identified ticks.

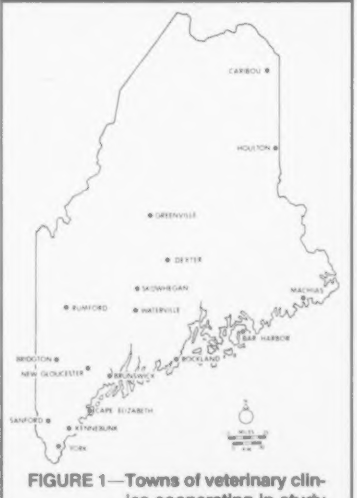

FIGURE 1—Towns of veterinary clinics cooperating in study (Dexter clinic also serves Greenville).

Materials and Methods

Ticks were submitted by veterinarians, physicians, and the public in response to published solicitations. They were also collected from natural hosts (live-trapped mice and tagged deer) by field workers and trained biologists. Tick identification was based on criteria established through

standard keys,[8–12] verified as necessary by the Smithsonian Institution, Washington, DC.

Sixteen high-volume veterinary clinics throughout Maine (Figure 1) were invited to collaborate on the basis of their proximity to recognized endemic regions (three southernmost clinics), to areas — primarily coastal — where specimens of *I. dammini* had been collected (five clinics from Cape Elizabeth to Machias), and to inland and northern regions with little or no history of the disease or its vector (eight clinics, one serving two towns). Each clinic was provided with sampling materials and questionnaires for each pet owner. Veterinarians were asked to provide an additional 1 ml of serum from 50 or more dogs tested for heartworm microfilaria between April 1 and June 1, 1989. The only selection criteria imposed were that dogs be over 6 months old, lifetime residents of Maine, and allowed, at least sometimes, to run in fields or woods. Frozen sera were shipped to Tufts University Veterinary Diagnostic Laboratory for analysis of antibodies to *B. burgdorferi* by enzyme-linked immunosorbent assay.[13] Questionnaire items included the dog's breed, age, sex, principal function, degree of confinement, and history of travel to endemic areas. Owners were also asked if their pets had previously been lame or treated for Lyme disease.

Results

Tick Collection

Of 1605 ticks examined in 1989, 585 were *I. dammini*. Of these, 218 were submitted and 182 were collected from 789 live-trapped small mammals, 78 from mist-netted birds, 39 from flagging, and 68 from 30 of 227 examined deer. Towns from which *I. dammini* and other tick species were received are shown in Figure 2. There is notable clustering along the coast: all but 5 of 53 towns producing *I. dammini* are within 20 miles of the tidal water.

To demonstrate that the high numbers of *I. dammini* submitted from coastal regions by the public were not the result of increased population density or vigilance in these areas, submissions of this tick

ODDS RATIO: Percent seropositive untravelled dogs vs. miles from the coast

RANGE(miles)	*O.R.*	*95% C.I.*	*P.*
0-20 vs 20+	3.89	1.11-11.96	0.03
0- 5 vs 5+	4.45	1.59-13.52	0.002
0- 5 vs 20+	4.81	1.36-14.50	0.01

FIGURE 6—Percent of traveled and untraveled dogs positive for anti-*Borrelia* antibodies vs. miles from the coast.

were compared to submissions of *Ixodes cookei*, which closely resembles *I. dammini*, is widely distributed in Maine, and is found more frequently on humans than *I. dammini*. Figure 3 shows that *I. dammini* comprised 64% of the combined *I. dammini/cookei* submissions within 5 miles of the coast, but only 10% of the submissions beyond 20 miles.

Canine Serosurvey

Sera from 828 dogs were received from 149 towns representing all counties. Thirty-six samples were positive, 28 of which were from untraveled dogs. Clinics with seropositive dogs were limited to primarily coastal areas in the southern half of the state (Figure 4). Highest seroprevalence (17%) occurred in dogs from the southernmost clinic. Positive untraveled dogs were also found in two inland communities, both on rivers but in nonendemic counties. No positivity was found among 102 dogs in the northern half of the state.

Figure 5 demonstrates that, with the exception of four towns, each of which had one positive dog, the home towns of positive dogs were all within a line arbitrarily drawn 20 miles (32.2 km) from tidal saltwater. Thirty-two of all 36 positive dogs (89%) and 25 of 28 traveled dogs (89%) were within this coastal zone; in fact, the great majority of both untraveled and traveled positive dogs were within the first 5 miles (8 km) of the coast, as shown in Figure 6.

Among the positive dogs there were more retrievers than in the negative group (55% vs 40%), median age was higher (6.3 vs 4.7 years), and a greater percentage of dogs were allowed to run free (61% vs 54%). The percentage of asymptomatic animals in each group was not significantly different.

Discussion

Comparison with previous studies (Table 1) indicates that even the highest level of canine seropositivity in Maine is less than that in other endemic states. While this may reflect relatively lower tick densities and infection rates, the presence of canine seropositivity so geographically coincident with the distribution of *I. dammini* cannot be overlooked as an indication of potential risk to humans in Maine or in other emergent areas. Subsequent to this study, eight additional cases of locally acquired human Lyme disease have been confirmed in Maine, all from coastal counties. Thus, both canine serology and vector tick distribution surveys have identified areas of human risk in advance of substantiation of that risk through passive human surveillance.

Canine anti-*Borrelia* serosurveys are simple, efficient, and economical. Coordination of sampling with annual heartworm testing is particularly advantageous because it provides a large, readily available population of dogs with known histories and a standard sampling time (April and May)—an important consideration given the marked seasonal variations in canine seropositivity that have been observed.[14, 18] The introduction of a canine Lyme disease vaccine in June 1990, however, may impair the future usefulness of dog serosurveys since dogs who receive it must be excluded from serosurveys. Anything beyond minimal vaccine use in an emergent area might introduce enough selection bias to limit the epidemiologic relevance of canine serosurvey data. ☐

Acknowledgments

This work was supported by grants from the Elmina B. Sewall Foundation, Davis Family Foundation, Simmons Foundation, and L. L. Bean, Inc. The authors gratefully acknowledge the assistance of Drs. Merle Weber and Joanne Lindenmayer of Tufts Veterinary Diagnostic Laboratory where the antibody testing was performed. They also thank State Veterinarian Dr. Chip Ridkey for his organizational advice, the veterinarians and staff of the 16 clinics for making this study possible through their interest and support, and Dr. W. Douglas Thompson for statistical analysis. Dr. Richard Dearborn of the Maine Insect and Disease Laboratory contributed data on tick distribution, and Dr. James E. Keirans, Research Entomologist at the Smithsonian Institution, confirmed tick species identification. Dr. Kathleen Gensheimer, epidemiologist, Maine Bureau of Health, provided data on reported human cases of Lyme disease.

NCHS to Publish New Data on Persons With and Without Health Care Coverage

The new study is entitled "Characteristics of Persons With and Without Health Care Coverage: United States, 1989" (*Advance Data* No. 201, National Center for Health Statistics, Centers for Disease Control, PHS, DHHS).

Highlights

An estimated 33.9 million Americans were without health care coverage in 1989. Health care coverage includes private health insurance, Medicare, public assistance (primarily Medicaid), and military or Veteran's Administration health benefits. Data were collected in the 1989 National Health Interview Survey, a nationwide household interview survey of the Nation's civilian, noninstitutionalized population.

People who lacked health care coverage included almost 40% of unemployed workers 18 years old or older (38.3 percent) and almost a third of people living below the poverty level (32.5 percent).

About 76.1% of the population were covered by private health insurance; 12.6% through Medicare; 6.2% by public assistance health care programs; and 2.6% were covered by military and/or Veterans' Administration health care programs.

Those without health care coverage increased from 13% in 1984 to 13.9% of the population in 1989. Although the proportion of people without coverage is greater for those below the poverty level, the increase in lack of health care coverage was greater for those above the poverty level during this period.

Situational Factors Associated with AIDS Risk Behavior Lapses and Coping Strategies Used by Gay Men Who Successfully Avoid Lapses

Jeffrey A. Kelly, PhD, Seth C. Kalichman, PhD, Michael R. Kauth, MA, Hilda G. Kilgore, MPH, Harold V. Hood, BA, Peter E. Campos, PhD, Stephen M. Rao, BA, Ted L. Brasfield, and Janet S. St. Lawrence, PhD

ABSTRACT

While most gay men have reduced behavior practices at high risk for HIV infection, there is growing evidence that many also lapse to unsafe sex. This study examined situational factors related to risk behavior lapses as well as coping strategies used by men who successfully resist lapse urges.

A convenience sample of 470 men patronizing gay bars or attending social organization meetings in four cities was surveyed. Forty-five percent of men were classified as "lapsers" (those who had had unprotected anal intercourse in the previous 6 months) and 24% were classified as "resisters" (those who successfully resisted urges to engage in this behavior). All provided information concerning the importance of factors related to the most recent occurrence of either unsafe sex or resisting unsafe urges.

Most episodes of unsafe sex occurred outside monogamous relationships and with partners of unknown HIV serostatus, although simply inquiring about partner serostatus was relatively common. Lapsers rated affectionate feelings and wishing to please a partner as well as spontaneity of unsafe sex as the most important situational factors surrounding high-risk behavior. Resisters of unsafe sex urges reported active cognitive self-guidance, experience in safe sex, and recall of both AIDS fears and safety benefits as their most important coping strategies.

Gay men who continue high-risk behavior may be overrelying on partner reports of negative serostatus. Lapse prevention approaches tailored to situations that create increased risk vulnerability must be developed. Teaching skills already used by men who successfully resist unsafe sex urges might be one approach. (*Am J Public Health.* 1991;81:1335–1338)

Introduction

Gay men in AIDS epicenters have made substantial risk reduction behavior changes.[1-5] However, these changes are difficult for many individuals to sustain. One third of homosexual men in Chicago who successfully initiate risk reduction later resume high-risk practices[6,7] Cross-sectional studies indicate that 30% to 40% of gay men in other cities still report engaging in unprotected anal intercourse in a given 3-month period.[8-10] Relapse is a concern even among gay men enrolled in San Francisco AIDS behavioral research cohorts, presumably one of the most AIDS-sensitized samples in the United States.[11]

Homosexual men who continue to engage in high-risk sex even occasionally are in great danger of contracting HIV infection. Gay men in large cities who have unprotected receptive anal intercourse with a single partner over 1 year are three times more likely to seroconvert than men who refrain from this activity and, with five partners, are 18 times more likely to develop HIV infection.[12] While lapses are the rule rather than the exception following initiation of change in all health behavior areas,[13-15] we were aware of no other population or health area where there is such a small margin for error and where even infrequent lapses carry such potentially grave health consequences.

Risk behavior relapse among gay men is predicted by younger age, lower education level, excessive intoxicant use, frequency of past risk behavior with multiple partners, and high reported past enjoyment associated with risky practices.[8,11,16,17] The present study more closely evaluated specific situational and social context factors surrounding risk behavior lapses as well as the coping strategies used by gay men who report successfully resisting high-risk behavior urges.

Method

Subjects

Subjects were 406 men who patronized gay bars and 64 men who attended social meetings of gay organizations in the spring of 1990 in four cities: Memphis, Tenn, Tampa, Fla, Mobile, Ala, and Binghamton, NY. Approximately 75% of men who were approached agreed to answer questions anonymously. The mean age of respondents was 31.0 years (SD=8.6) and the mean education level was 14.9 years (SD=2.2); 91% of the sample was White and 9% was Black, Hispanic, or of other racial or ethnic backgrounds. The city samples did not differ significantly in demographic characteristics.

Measures

Respondents described their sexual behavior over the preceding 6 months including frequency and number of partners for unprotected anal intercourse, both receptive and insertive. Forty-two percent of men who engaged in unprotected anal intercourse were the insertive partner, 35% the receptive partner, and 23% were both insertive and receptive during their most recent behavior. Multivariate analysis of variance revealed no significant difference between those who were the in-

sertive vs receptive partner in importance ratings for lapse situation items, so the insertive and receptive groups were combined for all data analyses. They were also questioned about number of partners and frequency for anal intercourse using condoms and about safer sex practices without penetration such as mutual masturbation and frottage (body rubbing). In addition, all men reported whether they presently had condoms in their pocket, car, and home.

TABLE 1—Situations Associated with the Most Recent Occurrence of High-Risk Behavior among Gay Men Who Report Unsafe Sex during the Previous 6 Months

Situational Descriptor	Mean (SD) Importance Rating
This partner was someone special to me	2.7 (1.3)
I wanted to please this partner	2.2 (1.3)
Once sex began, we got caught up in the passion of the moment	2.2 (1.2)
No condoms were nearby at the time of sex	2.0 (1.3)
Using a condom seemed impersonal	1.9 (1.1)
Using a condom would have reduced sensation/pleasure	1.9 (1.2)
Stopping to use a condom would have interrupted sex	1.8 (1.1)
I had a strong urge to have anal intercourse without a condom	1.8 (1.1)
It was hard for me to refuse having anal intercourse	1.8 (1.1)
It was a long time since I had anal intercourse without a condom	1.8 (1.1)
I had a lot to drink or used drugs and wasn't clearheaded	1.7 (1.1)
Condom use implies a lack of trust	1.5 (0.9)
It was embarrassing for me to suggest using a condom	1.5 (0.9)
I felt no control over what we did	1.5 (1.0)
I am not able to change my sex practices	1.5 (0.9)
I was feeling depressed, lonely, or upset at the time	1.4 (0.9)
This partner pressured me not to use a condom	1.4 (0.9)
It was too hard to get the condom package open	1.3 (0.7)
I didn't have the energy to use a condom	1.3 (0.6)
I pressured this partner not to use a condom	1.2 (0.6)
I was too embarrassed to buy condoms	1.2 (0.7)

Note. Importance ratings made on scale from 1=not a factor to 4=a big factor.

TABLE 2—Coping Strategies Reported to Be Used by Gay Men Who Successfully Resisted Urges to Engage in Unsafe Sex during the Previous 6 Months

Coping Strategy	Mean (SD) Importance Rating
I remembered information about AIDS and safer sex	3.6 (0.9)
I thought about how important it is to be in good health	3.5 (0.9)
I was afraid of getting (or giving) the AIDS virus	3.5 (1.0)
I reminded myself to stay safe before or during sex	3.4 (1.0)
I knew how good I'd feel about myself later if I stayed safe	3.3 (1.1)
I didn't want to worry about AIDS after sex	3.3 (1.1)
I am experienced in safer sex	3.3 (1.0)
I decided ahead of time what I would or would not be willing to do	3.2 (1.0)
I actively guided our actions to stay safe	3.1 (1.0)
The scare of knowing people with AIDS motivated me to be safe	3.1 (1.2)
I told this partner we needed to practice safer sex	2.9 (1.1)
I wanted this partner to know I was health conscious	2.9 (1.2)
I kept condoms nearby	2.9 (1.2)
I told this partner I didn't want to have unprotected intercourse	2.9 (1.2)
We switched from something that was getting risky to something safer	2.5 (1.2)
Safer sex was as good as intercourse without a condom	2.5 (1.2)
Safer sex was expected by this partner	2.4 (1.3)
I didn't drink or use drugs much before sex so I could be clearheaded	2.3 (1.1)
This partner told me he didn't want to have unprotected intercourse	2.3 (1.2)
This partner told me that we needed to practice safer sex	2.2 (1.3)
I didn't want other people to find out that I might have unsafe sex	2.0 (1.2)

Note. Importance ratings made on scale from 1=not a factor to 4=a big factor.

Respondents who reported engaging in unprotected anal intercourse in the previous 6 months ("lapsers," n=209, 45% of the sample) described, for the most recent occurrence of high-risk behavior, exclusivity of relationship with the partner, knowledge of own and partner's HIV serostatus, difficulty in maintaining safer sex practices, and percentage of anal intercourse occasions when condoms were used in the previous year. These men then rated the importance of 21 situational factors associated with the most recent occasion of high-risk behavior. As Table 1 shows, these items assessed environmental and setting factors, feelings toward the partner, coercion, physiological and emotional state, management of sudden urges, and self-control.

A second set of men were those who reported successfully resisting temptation to engage in unprotected anal intercourse in the previous 6 months ("resisters," n=116, 24% of the sample). (Men who reported no occurrence of unprotected anal intercourse *and* no temptation to engage in the practice were not studied here.) This group of men rated the importance of 21 coping strategies that may have been used on the most recent occasion when high-risk urges were resisted. Table 2 lists these items, which include risk reduction self-prompts; environmental modifications; active use of alternative behaviors; cognitive statements emphasizing benefits, fears, or beliefs of personal efficacy; and social expectations to avoid risk.

Results

As Table 3 shows, men reporting high-risk behavior were younger than those who reported resisting unsafe sex urges, had less education, and had had more male sexual partners in the previous 6 months. Groups were comparable in reporting having condoms in their pocket, car, or home and reported similar difficulty levels for remaining safe during sex.

Table 1 presents the mean importance rating for each situational descriptor associated with high-risk behavior by men who reported lapses, ranked from most to least important. Factors most critical to lapses were positive emotional feelings for the partner, wishing to please the partner, not having condoms nearby at the time of sex, becoming "caught up in passion of the moment," and negative connotations about condom use. As Table 2 shows, men who resisted high-risk urges reported the following as their most important coping strategies: cognitive reminders to re-

TABLE 3—Characteristics of Men Who Lapsed to Unsafe Sex and Men Who Successfully Resisted Relapse Urges during the Previous 6 Months

Characteristic	Lapsers (n=209)	Resisters (n=116)	95% CI[a]
Mean age in years (SD)	29.4 (7.6)	31.9 (8.4)	29.5–31.3
Mean educational level in years (SD)	14.6 (2.1)	15.6 (2.0)	14.7–15.2
Mean number of different male sexual partners in previous 6 months (SD)	4.5 (7.6)	3.4 (4.2)	3.4–4.8
Percentage of men reporting having condoms in their			
Pocket or wallet	29	27	—
Car	42	37	—
Home	84	93	—
Mean personal difficulty rating for remaining safe during sex (SD)[b]	2.6 (1.2)	2.5 (1.1)	2.3–2.8
Mean percentage of intercourse occasions when condoms were used during previous year	44	—	—

[b] Difficulty ratings made on a 5-point Likert scale from 1=very easy to stay safe to 5=very difficult to stay safe during sex.

TABLE 4—Relationship between Knowledge of Own HIV Serostatus and Knowledge of Sexual Partner's Serostatus among Men Reporting Occurrence of Unprotected Anal Intercourse

	Knowledge of Partner's HIV Serostatus			
Knowledge of Own HIV Serostatus	Didn't Know Partner Serostatus (n=97)	Partner Knew Was HIV Positive (n=5)	Partner Said He Was HIV Negative (n=61)	Saw Evidence Partner Was HIV Negative (n=35)
Not tested (n=55)	44 (22%)	1 (0.5%)	9 (4.5%)	1 (0.5%)
HIV positive (n=10)	7 (4%)	1 (0.5%)	2 (1%)	0 (0%)
HIV negative (n=133)	46 (23%)	3 (1.5%)	50 (25%)	34 (17%)

Note. Chi-square=40.1, df=6, $P < .0001$ for the association of knowledge of own serostatus and knowledge of partner's serostatus.

main safe during sex, self-statements regarding fear and avoiding worry, identifying the benefits of safety and good health, and experience and competence in actively guiding safer sex.

To examine the context of high-risk episodes, relationship status and serostatus knowledge between partners were also explored. Most high-risk activity (57%) took place between nonexclusive and casual partners; 43% occurred with partners described as exclusive, although the mean duration of the relationships was only 12.5 months. Table 4 shows the distribution for high-risk behavior in relation to knowledge of one's own and one's partner's HIV serostatus. Nearly half of the respondents who engaged in high-risk behavior had no knowledge of their partner's HIV serostatus; an additional 31% reported that the partner simply said he was HIV negative. In less than 18% of instances did respondents report first-hand knowledge of partner's HIV-negative status and, even when high-risk behavior occurred with a partner described as exclusive, two thirds of these men said they did not know both their own and their partner's serostatus. In general, knowledge of one's own negative status was related to a greater likelihood of inquiring about a partner's HIV status.

Discussion

Nearly one half of respondents in this sample had engaged in unprotected anal intercourse in the previous 6 months, usually with nonexclusive partners of unknown HIV serostatus. Even men who engaged in high-risk behavior appeared cognizant of risk: well over 80% said they had condoms at home and lapsers used condoms almost half the time. In addition to the association of risk behavior with affectionate feelings toward the partner and spontaneity of risky sexual practices, a large proportion of lapsers accepted partner claims of negative HIV status or their own past negative result. Among persons who continue to engage in high-risk behavior, past negative HIV results of self or partner, even if accurate, carry little current protective value. Approaches are needed that better prepare gay men to anticipate and handle lapse temptations, counter misconceptions that may perpetuate vulnerability to lapses, and stress the importance of maintaining consistent behavior change. These results indicate that resistance to lapses is related to active use of cognitive self-guidance, recall of both AIDS fears and safety benefits, and experience in safer sex. Although the current study is limited by its use of a convenience sample of unknown generalizability, respondent self-reports of behavior, and analysis only of "within-group" patterns, it highlights the need for further study of ways to prevent risk lapses in populations vulnerable to HIV infection. ☐

Call for Papers on Issues and Innovations in Financing and Reimbursement of Health Promotion and Education Programs

Health Education Quarterly, the official journal of the Society for Public Health Education, announces a call for original manuscripts for a theme issue on "Issues and Innovations in Financing and Reimbursement of Health Promotion and Education Programs." Manuscripts on a wide variety of topics addressing this theme are solicited. All manuscripts will be peer-reviewed by a guest editorial board. Manuscripts may address the following:

- Innovative financing strategies for patient education and health promotion
- Legislative initiatives to finance health promotion
- Citizen action (referenda etc.) to finance health promotion
- Quality assurance issues in health promotion related to financing and reimbursement
- Patient education reimbursement
- Health education and cost containment
- Innovative linkages with Medicaid and Medicare
- Federal and state health promotion policy related to funding, financing, and reimbursement
- Payment strategies in various medical care settings
- Consumer payment for services
- Effects of reimbursement on the demand for and supply of patient education services
- Implication for financing of patient education under proposed changes in outpatient payment
- Other

Review papers, case studies, research studies, policy analysis, and other types of papers will be accepted. Papers covering financing, reimbursement, payment, and funding of health promotion and education in all settings, including worksite health promotion, patient education, community health promotion, and other settings are encouraged.

Papers are due December 15, 1991. Please submit a letter of intent, if possible, by July 15, 1991 (papers submitted without a letter of intent will still be accepted but letters of intent will help in the review process).

Please send the letter of intent and manuscript to Randy Schwartz, MSPH, Director, Division of Health Promotion and Education, Bureau of Health, Department of Human Services, State House Station 11, Augusta, ME 04333.
